(a) The radionuclides considered in this chapter move very freely in the environment and living organisms. Therefore, there is little difference between inhalation and other routes. For this reason the chapter reviews work by several routes of administration since they apply to inhalation problems as well.

Capsule Chronology

- 1938 Tritium discovery announced by Alvarez and Cornog. Produced by accelerators.
- 1942 Failla calculates tolerance concentrations for radioactive gases in air. Consideration given to 5.4-day xenon in design of pilot plant for MED^(a) operations (Wollan and Stephenson, Met Lab).
- 1943 Radioxenon causes special concerns as possible off-gas from the Chicago pile. Abrams studies radioargon as surrogate for radioxenon. Hazards of inhaled iodine vapor recognized at Met Lab, Chicago. Hamilton indicates that inhaled ruthenium particles are much more hazardous than ⁷⁰Kr, ¹³¹I, or ¹²⁷Xe (Berkeley).
- 1944 Xenon exposure unit constructed and mice exposed at Clinton Labs (Cole). Dose to lung high, but effects minimal.
Experiments at Chicago with ¹³¹I (Daily, Wender, and Abrams). Idea generated for use of stable iodine to block thyroid uptake of iodine vapor (Berkeley).
- 1947 Work at Berkeley measures tissue contents of xenon after exposure.
- 1948 Brues and Buchanan expose mice to atmospheres of ¹⁴C (Argonne).

EARLY POSTWAR YEARS

- Hanford work on tritium and iodine vapor begins (Thompson and Ballou; Kornberg; Bustad; Bair); a major effort.
- Work on radioxenon continues, but attention focused more on radio-krypton (mostly ⁸⁵Kr). Several laboratories. Calculations indicate skin dose will exceed lung dose.
- Los Alamos work on inhalation and skin-absorption of tritium in man (Pinson, Langham). Skin absorption work at Hanford (Kornberg).
- Argonne work with ¹⁴C and tritium continued.
- Study of behavior of noble gases (stable) in man (Tobias at Berkeley).
- Early 1950s Large quantities of tritium found to be produced in fusion weapons explosions, far exceeding amounts produced in fission. Also, tritium assumes importance as an ingredient of the fusion devices, and special reactors are built to produce it.
- 1951 Jennings and Brues compare toxicity of tritium to that of x rays (Argonne).
- 1952 Further work by Brues on toxicity of tritium (Argonne).
- 1953 Concentrated work at Los Alamos on RBE of tritium (Furchner and Storer; later Spalding; Langham and Anderson; Worman).
- 1954 Los Alamos work on toxicity of tritium continues with animal exposures (Langham and Anderson).
- 1955 Libby identifies ¹⁴C in nature, estimates amount present.

(a) For abbreviations and acronyms, see Appendix D.

- 1955, 1957 Furchner, Anderson, et al.; Storer et al. (Los Alamos) work on acute effects of tritium.
- 1957 Comparison of tritium to ^{60}Co gamma rays given at an exponentially declining dose rate (Furchner at Los Alamos).
Windscale accident releases large quantities of radioiodine, much in vapor form (details in chapter 11).
Work on solubility of radon in body fat (Hursh and Nussbaum at Rochester); see chapter 3.
- 1958 Willard and Bair compare iodine vapor and silver iodide particles (Hanford).
- 1960s Growth of work with tritiated and iodinated macromolecules—see chapter 20 (M.D. Anderson Hospital, Brookhaven, Lawrence Livermore, Oak Ridge, Ohio State, Rochester).
Peculiar physiological effects of noble gases noted but at high partial pressures.
Experimental work at Savannah River on tritium in man (Reinig, Butler, Sanders, et al.).
- 1962 Federal Radiation Council considers inhalation of iodine vapor.
Berkeley work with tritium (Siri and Evers).
Richmond work on tritium (Los Alamos)—no actual inhalation studies.
- 1963 Hanford Biology Symposium includes papers on iodine vapor.
- 1965 Work with tritiated macromolecules shows they can produce cancer (Dewey et al. at M.D. Anderson).
- 1966 Canadian reports on behavior of tritium in man (Osborne).
- 1968 Snyder report of excretion rates and calculated doses in Oak Ridge employee who inhaled HTO.
- 1969 First reports of Cahill's work on tritium toxicity (Rochester and EPA, North Carolina). Includes effects on embryo and progeny over two generations (published in 1973). Possible synergistic effects with lead.
- 1970 Woodard's review of tritium (AEC series).
Lovelace work on iodine inhalation.
- 1970s Experimental work with krypton (Kirk at Rochester and BRH^(a); Ballou et al., Battelle; Ellis at Brookhaven). Early work concerns mostly kinetics of movement in tissues and body fluids. Later work turns to effects (Kirk, Rehnberg and Morken at Rochester and BRH).
Hanford work with krypton using rats, dogs, and sheep, both pharmacokinetics and effects. No tumors or other cancers induced in adults, but skin lesions occur in newborn rats and some became carcinomas. Reports continue into the 1980s and are still appearing (Ballou, Willard, et al.).
Brookhaven work on krypton reports on sixteen human subjects (Ellis et al.). Concentrates on metabolism.

(a) Later work was under EPA auspices.

- 1971 Tritium Symposium at Las Vegas, published 1973 (Moghissi and Carter, PHS-AEC-EPA).
- 1973 Bernard devises new models for ^{14}C (Oak Ridge).
Reports on Swiss luminizers (Seelentag). Two fatalities.
Also reports of urinary excretion of tritium in Czech luminizers (Houšková et al.).
- 1974 Evans's book on tritium (U.K.).
Anderson and Langham on acute toxicity of tritium (Los Alamos).
- Mid-1970s et seq. Brookhaven program on tritium (Carsten, Comerford, Cronkite, et al.). Very broad.
- 1975 Book on tritium by Moghissi and Carter. Includes work on luminizers who used tritium instead of radium (FDA auspices).
Life-span work with tritium in rats by Cahill (EPA, North Carolina). Includes possible behavioral effects and synergistic effects with lead.
Reactor Safety Study concludes that iodine vapor could be a significant hazard in a major reactor mishap (Rasmussen).
- 1976 Tritium compared to plutonium in producing chromosome aberrations (Blaylock and Trabalka at Oak Ridge).
Dobson's work on RBE for tritium compared to ^{60}Co gamma rays in short versus protracted exposures (Berkeley).
- 1977 Decided that internal doses (to thyroid) are much more important than external doses for iodines in vapor form.
Brookhaven work on tritium in biologically important molecules. See also chapter 20 (Bond, Carsten, Commerford, Cronkite, Feinendegan, et al.).
- 1978 IAEA symposium on tritium (published in 1979).
- 1979 NCRP report on tritium in the environment.
Oak Ridge work on genetic effects of tritium (Russell).
Review of tritium in Swiss watch industry.
Comparison of late effects of x ray, ^{137}Cs , and tritium (Carsten and Cronkite at Brookhaven).
- 1980 Book (by Davis) calculates thyroid doses as a function of age and mode of exposure. Inhalation sometimes, but not always, the critical mode.
NCRP report on ^{129}I .

Chapter 10

The Respirable Gases

Overview

The research reviewed in this chapter includes some of the most benign of the radioisotopes from a toxicological point of view (with the exception of iodine) and thus stands in sharp contrast to the inhaled particles we considered so exhaustively in the previous chapter. This difference is partly because they move freely and rapidly in and out of the body and tissues. There is relatively little tendency for long retention or the build-up of significant deposits. The difference is also partly because the radioelements concerned are, in general, low-energy beta emitters (again with the exception of iodine). And it is partly because some of the members of this group are almost inert chemically.

Nevertheless, the respirable gases have posed some unique problems that required experimental investigation. The effort during the Manhattan Engineer District days was relatively small next to some of the enormous efforts in other areas of pulmonary radiotoxicology. Yet it was important, especially the work on iodine.

When the fusion process was developed, tritium assumed considerable importance, and much research was necessary to determine the behavior of tritium as an element (T), as a gas (HT), and as tritiated water (HTO). It was also necessary to examine the toxicologic aspects of tritium when incorporated into biologically important molecules. The same applied to radioiodine and to radiocarbon.

In contrast to the large, highly organized projects in inhalation toxicology we saw in chapter 9, the research on the radioactive respirable gases was done more on an individual entrepreneur basis. Yet most of the work was carried out in government laboratories or on government contracts. Much of the iodine work started at Hanford. Tritium became a major activity at Argonne, Brookhaven, Los Alamos, the Environmental Protection Agency laboratories, and early at Hanford, with Rochester participating largely through graduate thesis projects.

The amount of scientifically interesting information derived from these researches (unfortunately treated very lightly herein) was almost in inverse ratio to the relative importance of these entities as exposure hazards. Yet, it is clear that it was important for both the researcher and the worker in industry to know what they were doing with even these mildly toxic radioactive substances.

I. Generalities

This second chapter on the inhalation toxicology of radioactive materials (pulmonary radiotoxicology) concerns materials and problems that stand in sharp contrast to the subjects of chapter 9. We deal here with elements that are either noble gases or that move freely enough in biological materials to have many of the characteristics of the noble gases. Although some of them form compounds of considerable importance, they are, for the most part, either broken down readily in the body or, for other reasons, exhibit considerable mobility. Consequently, retention times are characteristically short.^(a) We see little of the long-term residence in target organs, little of the formation of aggregates or colloids, little of the attachment to vector aerosols, and little of the other properties characteristic of inhaled particles. As a result of their mobility and their generally low-energy beta emissions, some of the most benign of the radionuclides from a toxicological point of view reside in this group.

Radioactive noble gases worthy of consideration are ^{41}Ar , isotopes of krypton, ^{222}Rn and ^{220}Rn , and the several isotopes of xenon. Other common radioactive substances that behave more or less like noble gases and fit the definition of respirable gas are iodine isotopes in vapor form, ^{14}C in carbon dioxide, and tritium as either tritium gas (^3H or T) or tritiated water ($^3\text{HO}_2$ or TO). All except radon and iodine have low-energy beta-particle emissions. The iodine beta can be considered as of intermediate energy.

Radon was discussed in chapter 3, although not much emphasis was placed on its behavior as a noble gas because of the importance of its radioactive daughter products. The others will be considered in the sections that follow, first in connection with the rather sparse work during the days of World War II and, later, on an individual basis in the years of growing concern and knowledge of their biomedical significance and behavior. Environmental behavior and problems of primary concern to ecosystems will be taken up in later chapters.

We will concentrate on the behavior and effects of these respirable gases on inhalation by mammalian species. However, many are so readily absorbed from the gastrointestinal tract, even the skin in some instances, that information gained using these other routes of administration can be applied as well to the inhalation route. Exceptions are where specific compounds of importance primarily in nuclear medicine are involved.

There have been no major projects built around these elements and compounds. Work was diffused (like the gases themselves) among a number of laboratories. There have been no major centers of action comparable to those we saw in chapter 9, although some individual investigators have concentrated their research in these areas. For this reason, we will arrange our discussion around the elements and the associated problems rather than laboratories.

II. The Respirable Gases in the Manhattan District Days

A. Noble Gases

We pointed out at the beginning of chapter 9 that the first biological experiments in the Manhattan Engineer District (MED) with inhaled materials of any

(a) Exceptions occur, as for example the labeled precursors of the nucleic acids, but they are not very important for inhaled gases. The chief exception is iodine in the thyroid.

kind concerned radioactive xenon. The concern for xenon arose from its production in reactors and the lack of easy means to trap it.

As part of an early Metallurgical Project monthly report from Chicago, Wollan and Stephenson (1942) discuss the amounts of "5.4-day"^(a) xenon (^{133}Xe) to be expected with operation of "The Pilot Plant" for one month and chemical processing of the products. The amount was 3×10^4 Ci, an amount that gave pause to those planning health protection in those early days. They calculated that man could safely breathe air having a concentration of this xenon isotope of 8×10^{-9} Ci/cm³. Thus, the 3×10^4 Ci produced would require 4×10^{12} cm³ of diluting air to bring the off-gases to this safe level. The Chicago workers concluded that this amount of dilution was feasible, but it had to be kept in mind.

In the same report, plans are mentioned for an apparatus to expose guinea pigs to radioactive gas, largely radioxenon, in Abbott Hall on the campus at the University of Chicago. In a report dated February 1943, the activities of K. S. Cole at Chicago with ^{127}Xe (36.4-day half-life) are described. These included attempts to determine ratios of effectiveness of radioxenon to fast neutrons and x rays. This work was built around materials expected to be released in the cooling air from the Clinton pile, but it seems also to have been aimed at experiments to be performed at Argonne (Stone 1943). Later in this same report, Cole reports on guinea pigs kept in radioxenon (^{127}Xe) at 0.1 mCi or 0.5 mCi/l. Although some of the animals died, dehydration, hypoxia, and other complications made it impossible to separate out any radiation effects. (The exposures were relatively short.)

By the May 1943 monthly report, R. Abrams (see chapter 9) was on the job at Chicago. Because radioactive xenon (i.e., ^{133}Xe) was not yet available in sufficient quantity, he substituted radioargon (^{41}Ar). This has a higher energy and shorter half-life than the xenon isotopes of interest at the time, but it was considered a reasonable substitute. Guinea pigs were given single exposures to progressively higher concentrations of ^{41}Ar in a bottle. Little biological effect ensued, which is not surprising since the total lung dose was between 1 and 2 r (Abrams 1943b). Similarly, no effect was seen after five exposures to ^{41}Ar at 300 mCi total dose (Abrams 1943a).^(b)

In August of 1943, a "Conference on Xenon Factor" was reported, which apparently took place at Chicago. This had little biomedical import except to close with a query as to how soon rabbits could be exposed to the products of "Cooper's solution process." In the monthly report for the same month, we find that a guinea pig exposed to 1.25×10^{-5} Ci/cm³ of ^{127}Xe died on the twenty-fifth day with average beta exposure to lung at 450 r. The cause of death was unknown. There was also some work reported on the possible use of gas mask canisters for removal of xenon from inhaled air. They appeared to be reasonably effective.

In the report for the month ending April 25, 1944, Cole (1944) tells of a unit installed at Clinton Labs for producing ^{133}Xe and the exposure of twelve mice. The highest activity concentration was 10^{-5} Ci/cm³, and the mouse receiving the

(a) The current figure for the half-life of ^{133}Xe is 5.245 days.

(b) Argon-41 is produced by neutron bombardment of normal atmospheric argon and was especially prevalent in early single-pass air-cooled reactors. Its short half-life (1.8 hr) and ease of dilution with the cooling air soon removed it from biomedical concern as a hazard.

longest exposure attained an average lung dose of 6,500 r^(a) (whole-body dose about 200 r). Six animals received 2,800 r to the bronchi and lungs over a period of 3.5 wk. They report no evidence of histological damage but do not indicate whether or not any significant time was allowed for effects to develop—probably not.

Subsequent Metallurgical Project reports were in the same vein insofar as work at Chicago was concerned. They continued to have trouble getting enough xenon for a good toxicological experiment.^(b) By the time they did get enough xenon, it was becoming apparent that other radionuclides posed much greater problems.

This view was probably based in part upon a letter from Joe Hamilton at Berkeley to C. M. Cooper in Chicago (Hamilton 1943a). By now (see chapter 6), the Berkeley group had prepared ⁷⁹Kr, ¹³¹I, ¹²⁷Xe, and a number of nongaseous fission products from material bombarded in the Berkeley cyclotron (Hamilton 1943b). To emphasize the relative importance of radioruthenium over some of the other nuclides, Hamilton states (as quoted in chapter 6), "I should like to point out in the first place that under these circumstances^(c) radio-ruthenium. . . is far more of a potential hazard than either the 8 day iodine or the 5 day xenon, since these elements have relatively short half-lives and their abundance at the time of chemical extraction may be many times less than that of the ruthenium" (Hamilton 1943a, p. 1). He goes on to cite preliminary results of experiments that show much longer retention of ruthenium in the lung than of either radioxenon or radioiodine. Hamilton's admonition was appropriate to the time when major new problems had to be addressed.

The Berkeley work tied closely to work being done in John Lawrence's laboratory on the behavior of the radioactive noble gases in human subjects. A direct determination of the xenon content of animal tissues was reported in work declassified in 1947 (Hamilton 1947). Rats were put into a desiccator with 2 mCi of ¹²⁷Xe^(d) in the gas phase with oxygen renewed by a bubbling device. After sixteen hours' exposure, the tissues were analyzed with precautions to lose as little xenon as possible. The gamma rays from the xenon were measured through the walls of the glass vials containing the tissues in paraffin. As expected, the tissues with the most fat had the most xenon. Figures are given for sixteen tissues and whole body. This led to determination of oil-to-water solubility ratios of a number of inert gases available as radioactive isotopes and the conclusion that differential uptake curves of xenon versus krypton or ⁴¹Ar provided a means of measuring the relative amounts of watery and fatty tissues in different individuals.

Radioactive krypton (⁸⁵Kr) has a half-life of 10.27 yr, a low-energy beta particle emission of $E = 0.250$ MeV, and a fission yield of 3×10^{-2} atoms per fission, high relative to many other fission products. However, it is so unreactive as to be regarded as perhaps the "most noble" of the noble gases. Little krypton escapes

(a) Note the reported doses here and on the previous page were in roentgens. This was before either the rep or the rad had general usage.

(b) The book by Dr. Hymer Friedell on the history of biomedical activities in the Manhattan Project, cited in chapter 9, notes exposure of rabbits as well as guinea pigs and mice as mentioned in these pages. Thus, enough was made to expose larger animals, but not for toxicology.

(c) One hundred days' operation followed by sixty days' cooling.

(d) The radioxenon was prepared by deuteron transmutation of ¹²⁷I.

from reactors in the absence of cladding failures. However, large quantities can be released during fuel reprocessing. By virtue of its lack of reactivity, it is very difficult to trap. The potential impact of its release on levels of worldwide contamination were appreciated in the later years of the war. Nevertheless, there is essentially no record that this author has been able to find of biomedical work with krypton during the MED days. Apparently work with xenon and argon gave the early workers all the cues they needed to make decisions about the radioactive noble gases. The fact was established that exchange was rapid in both directions and biological half-lives were short, except for fat.

B. Iodine Vapor

It must be remembered that iodine isotopes had been around for some time before World War II or the Manhattan Project (chapter 5). The pioneer work had already been done, much of it at Berkeley and Massachusetts Institute of Technology (MIT). It was familiar territory compared to the new fission products and the actinides. It is not surprising, therefore, that there was not a large effort devoted to iodine during the MED days, except for the new isotopes that appeared after fission and continuation of the clinical applications.

The potential hazard of inhaled ^{131}I is addressed by calculation in the Metallurgical Project monthly report dated May 1943. Experimental work by inhalation had to await the availability of ^{131}I , a considerable improvement over ^{128}I (with its twenty-five-minute half-life) used in earlier noninhalation work (see chapter 5).

Experiments involving both sufficient material and enough animals for more than spot-check-type results were done about 1944 at Chicago (Dailey, Wender, and Abrams 1945). They used a manifold arrangement similar to that shown in figure 9.5C of chapter 9.^(a)

The abstract of this document gives the high points as seen by the authors:

Radioactive ^{131}I was obtained from pile bombarded tellurium, from sump water from the extraction plant at Site X, and from fumes evolved from solution of bombarded slugs. An oxidizing agent (usually KIO_3 or $\text{H}_2\text{O}_2 - \text{FeSO}_4$) was added to a solution of radioactive iodide and iodine gas was thus evolved. The radioactive iodine gas was mixed with air and passed through a manifold from which 21 anaesthetized rats breathed. Tissues were wet-ashed for measurement of activity due to ^{131}I .

Results of two experiments indicated that about 10 percent of the inhaled I_2^{131} was retained by the rats. Of that which was retained at the end of a 30 minute exposure only five percent was in the lung and some of this was probably in pulmonary blood. Hence absorption of I_2 from the lung was practically instantaneous. The thyroid contained 10 percent of the retained iodine at 48 hours; the remaining 90 percent was excreted in the urine. The fate of iodine absorbed from the lung is similar to that of ingested iodide.

(Dailey, Wender, and Abrams 1945)

Distribution to the tissues and excretion of iodine taken in as a vapor are shown in figure 10.1, taken from the Chicago work.

(a) Iodine vapor is a lung irritant (more effective than chlorine). As a result, relatively little experimental work had been possible by inhalation before the advent of radioisotopes of iodine. These made work with the vapor feasible by virtue of the much smaller quantities required.

FIGURE 10.1. Distribution of inhaled $^{131}\text{I}_2$ in rats. (Redrawn from Dailey, Wender, and Abrams 1945.)

At Berkeley, the iodine isotopes formed in nuclear fission were part of the large enterprise involving parenteral and ingestion routes described in chapter 6. As with other very soluble compounds, the behavior after ingestion was considered a good substitute for inhalation work. Perhaps for this reason, experiments specific to iodine vapor do not appear in the MED work at Berkeley.

In 1944, a good summary of the status of radioiodine in physiology and metabolism was prepared by the Berkeley group (Hamilton 1944).^(a) This is clinically oriented and concerns largely data from man. A postscript on protection of personnel around the new reactors is the suggestion for taking 100 mg of stable iodine per day to block absorption of iodine vapor by the thyroid. We have no records of this having been done.

At the very end of the MED days, quite large quantities of ^{131}I were becoming available. As part of the transition to peacetime enterprises, laboratories like Berkeley began greatly expanded programs for radioiodine in diagnosis and therapy. These do not concern inhalation problems and will be reserved for our discussion of the relationships between internal emitter toxicology and nuclear medicine.

C. Other Respirable Gases

While the presence of tritium and tritiated water vapor and of ^{14}C as radioactive carbon dioxide was recognized in the mixed fission and activation products, their amounts and potential toxicity were considered of minor importance in

(a) This report was classified "Secret" even though it was made up entirely of quotations from open literature publications. Nothing could get out that gave any hint that radiation problems might play a part in the interests of the Manhattan District, a fact that accounts for many apparently stupid procedures.

relation to the cadre of new radionuclides requiring study in the Manhattan Project laboratories. Essentially no work on the toxicology of tritium, etc. was done during the MED days.

III. Postwar Work with the Noble Gases and Iodine Vapor

A. The Noble Gases, Especially Krypton and Xenon

1. Computational Approaches

In contrast to the relative paucity of biomedical investigations on krypton in the MED work, a considerable effort was mounted in the early postwar years. Plans for a nuclear power industry of considerable magnitude and anticipated fuel reprocessing activities, both civilian and military, focused attention on the krypton (mostly ^{85}Kr) that might be released. Work on xenon isotopes continued.

By this time, the potential for chemical reactions of the noble gases with fluorine, oxygen, etc., had been discovered along with the quasi-physical process of clathrate formation.^(a) Xenon, the most reactive of the noble gases, was postulated to produce clathrate-type side chains with body proteins—a possible explanation for its narcotic effects.

Projections of the accumulation of radioactive gases in the atmosphere were made by many laboratories and cognizant agencies of government. Acid treatment of fuel elements releases many substances in gaseous form. Krypton-85 and tritium are released in sufficient quantity and possess long enough half-lives (10.76 and 12.26 yr, respectively) to accumulate to a considerable degree if releases are not controlled. For example, about 5,000 Ci of ^{85}Kr may be released per batch of spent fuel processed at an installation such as the Nuclear Fuel Services operation at West Valley, New York.^(b)

Thus, the total accumulation could be in the megacurie range. Indeed, Whipple (1969) estimated that ^{85}Kr emission might limit U.S. nuclear power activities to about 150,000 megawatts of electrical energy (MWe).

Radioactive krypton and xenon are also produced in nuclear explosions. One source (Unruh 1970a,b) calculates 5×10^4 Ci of ^{85}Kr have been produced by nuclear explosives. This is small compared to the 1,300 Ci per day per 1,000 MWe from reprocessing of fuels from nuclear power plants. Estimates of total free-world production of ^{85}Kr varied considerably (Kirk 1972) even in the 1960s and early 1970s. With the failure of nuclear power to develop as anticipated, most projections are probably now too high. Yet, we find it useful to quote some round numbers: by 1980, about 200 megacuries; by 1990, about 1,000 megacuries; by 2000, about 3,500 megacuries.

Figures for other noble gases are lower because of shorter half-lives (e.g., ^{133}Xe , 5.2 days) or lower fission yield.

(a) A clathrate is a solid that incorporates a gas into voids in its crystal structure. Both water (hydrates) and organic solvents exhibit such behavior. Kirk (1972) pictures the structure of a hydroquinone clathrate.

(b) This facility is not in operation now. Neither has the nuclear industry grown according to early projections. Nevertheless, the calculations are informative.

What biological significance do these apparently enormous amounts have, especially as an inhalation hazard? Still using the computational approach, we recognize the enormous dilution accomplished by the earth's atmosphere. Hendrickson at Battelle (1970) estimated, using data from several sources, that the concentration represented by total inventories toward the top of the global estimates would be on the order of $3 \times 10^{-7} \mu\text{Ci}/\text{cm}^3$. This is one-tenth of the then-existing maximum permissible concentration for continuous occupational exposure to ^{85}Kr of the International Commission on Radiological Protection (ICRP) and the National Council on Radiation Protection and Measurements (NCRP). This amount would yield annual doses to the whole-body surface of 500 mrem, to the skin of 300 mrem, and to the lung of about 12 mrem. The dose to lung on inhalation was calculated by Whitton (1968) of the United Kingdom at about 5 mrem from ^{85}Kr in the lung and 7 mrem from external radiation.

These and other calculations have resulted in the conclusion that the doses to the lung from noble gases in the environment are small in comparison to those associated with the external radiation from immersion in a passing cloud of the gases. Skin becomes the critical organ for ^{85}Kr for example. Doses could be 0.5 rem per year at the skin surface, 0.3 rem per year in the shallowest layer of live skin; to be compared to 0.005 rem to the internal surface of the lung and 4×10^{-7} rem per year to the lens of the eye—all from continuous immersion in air with a concentration of $3 \times 10^{-7} \text{ Ci}/\text{cm}^3$ of ^{85}Kr (Hendrickson 1970).

The idea that the submersion dose is controlling has taken over for all of the noble gases except, of course, radon, which presents an entirely different problem. Officially it is an "infinite hemispheric cloud." Walter Snyder, of Oak Ridge National Laboratory, the dean of the calculators for internal emitter standards, produced several papers with his colleagues, just before his untimely death, on the doses from various scenarios of immersion in clouds of released gases. An example is Bernard and Snyder (1975), which concerns dose on inhalation of noble gases.

What of the noble gases dissolved in body fat? Using ^{85}Kr again as an example, we find that calculated internal dose in the fat can indeed be over two orders of magnitude higher than the lung dose from the beta-particle component (the gamma component is much lower). Fat is, of course, a very radioresistant component of tissues. But the external dose is yet another order of magnitude higher than the dose even to fat (Diethorn and Stockho 1972). Hence, the importance of immersion over inhalation persists even if the high solubility in fat depots is considered. The primary effect of the fat is to slow release of residual amounts after the easily diffusible portions have left the body.

The noble gases have been used for many years in numerous procedures in medicine (see, for example, Bennett et al. 1965; Wagner 1965). Most of these are diagnostic and concern respiratory or circulatory functions or determination of total body fat. In these cases, the gas may be given in radioactive form for ease of measurement and is, of course, inhaled. No immersion dose is involved. Lassen (1964) from Copenhagen has assessed tissue radiation doses from two noble gases, krypton and xenon, as well as tritium given in this manner. Tracheal mucosa received up to 96% of the total dose; lung up to 17%; adipose tissue between 8% and 9% depending on body build; gonads around 1%; and other tissues between 1% and 2% of the dose from ^{133}Xe inhalation. Corresponding figures for ^{85}Kr inhalation were higher for lung but lower for all other tissues, including tracheal mucosa.

These calculations do not mean any real change in the evaluation of hazard from noble gases. As calculated by Lassen (1964), the actual doses are still at a maximum of about 100 mrad from inhalation of a concentration of $1 \mu\text{Ci}/\text{ml}$ for one minute, which is equivalent to an injection of 5 mCi of the isotope.

The general result of all the calculations can be summarized in the broad generalization that inhalation of millicurie amounts of the common radioactive noble gases results in millirad doses. This stands in stark contrast to the phenomena we saw in chapter 9.

2. Experimental Approaches

The experimental work concerns largely the tissue mobility of noble gases, seen amply in the various clinical applications in nuclear medicine, better determination of partition coefficients in tissues, and a small amount of work on effects.

Experimental programs on krypton began almost simultaneously, one by Kirk and Morken started at Rochester and continued at the Environmental Protection Agency (EPA) Regional Laboratory in Montgomery, Alabama (Kirk);^(a) another at Hanford in work by Ballou, Willard, and colleagues; and a third at Brookhaven on the kinetics of inhaled krypton in man (Ellis et al. 1977). It is not clear why the midseventies should have nurtured these fairly substantial efforts after years of relative inactivity. The *raison d'être* given by Ballou (1976) is the continuing expansion of the nuclear industry and the fact that most hazard estimates for elemental tritium^(b) and ^{85}Kr were based on dose calculations derived largely from physical rather than biological data. Kirk got into the field for some of the same reasons, but, in addition, krypton made a good thesis study area and his supporting agency apparently encouraged him to study the noble gases. It is likely that interest was expressed at the Atomic Energy Commission (AEC) in having more work on krypton. Kirk and Morken, publishing from North Carolina and Rochester, respectively, studied the saturation and desaturation kinetics for ^{85}Kr in guinea pigs breathing a krypton-air mixture (Kirk and Morken 1975 and earlier work quoted therein). There were usually four components to the curves with half-times ranging from less than 2 min to between 88 and 178 min. Association with various conceptualized compartments was reasonably good, except that the half-times were longer than predicted.

A glimpse of the distribution of krypton in man at from 0.45 to 27.85 hr after administration is shown in figure 10.2. This information was obtained by whole-body-counting techniques.

A discouraging aspect of all of this work, and the results of a thorough review of the literature, was the variability of the rates. They varied not only among individual animals of a given species but in the same animal at different times. However, it was apparent that the average times required for saturation and

(a) William P. Kirk, a Public Health Service officer, was assigned to the University of Rochester for Ph.D. studies in the early postwar years. He produced a Ph.D. thesis on krypton effects working with Donald A. Morken, whom we met in the radon chapter. The review cited was produced from Southeastern Environmental Radiation Laboratory of the then Bureau of Radiological Health at Montgomery, Alabama, where Kirk continued experimental work in the field for many years. The review was based in part on his Ph.D. thesis. In the 1970s, Kirk moved to the Experimental Biology Laboratory of the EPA National Environmental Research Center in Research Triangle Park, North Carolina.

(b) The original announcement of the new project included tritium.

FIGURE 10.2. A typical profile distribution of ^{79}Kr in man, based on the coincidence counting mode of the whole-body counter. (Redrawn from Ellis et al. 1977. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1977.)

desaturation are related to body size, being slower, as might be expected, in larger species. This work harks back to early postwar work by Tobias et al. at Berkeley (1949), which pioneered some of the current ideas concerning the behavior of noble gases in vivo.^(a,b)

Is it possible to produce acute radiation effects with these relatively benign radioactive noble gases? Indeed it is. We should remember that even high activity concentrations do not represent much mass. Kirk, Rehnberg, and Morken (1975), publishing again from the EPA center at Research Triangle, North Carolina and the University of Rochester, conducted a thorough study of the acute lethality of ^{85}Kr . They used nose-only exposures with individual exposure chambers attached to a ventilated plenum, much as described in the previous chapter. Exposures lasted twelve hours, with periodic purging of the body chambers to prevent accumulation of krypton by leakage around the latex collars. The observation period was sixty days.

- (a) Table 1 in the Kirk publication provides a handy summary of the compartmental half-times for ^{85}Kr obtained over years of work in many laboratories.
- (b) At Rochester, Nussbaum and Hursh (1957) determined the preferential solubility of radon in body fats in the midfifties. The partition coefficients were similar to those of other noble gases.

A typical lethality curve is given as figure 10.3. The exposure is given as a time-concentration unit ($\mu\text{Ci}/\text{cm}^3$)·hr, and the median lethal exposures calculated by two methods are given in the body of the graph.

FIGURE 10.3. Lethality curve—guinea pigs exposed to ^{85}Kr via respiratory route. (Redrawn from Kirk, Rehnberg, and Morken 1975. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1975.)

Doses, shown below,^(a) were calculated from knowledge of the partition of krypton in the tissues and on the assumption that a steady state existed during exposure with saturation and desaturation kinetics being mirror images of each other.

Exposure	Estimated Beta Dose (rad)		
	Bone Marrow	Whole Body	Lungs
4450 ($\mu\text{Ci}/\text{cm}^3$)·hr. (The median lethal exposure by graphical solution)	316	340	7876
4511 ($\mu\text{Ci}/\text{cm}^3$)·hr. (The median lethal exposure by least-squares method)	320	345	7984

(a) Modified from Kirk, Rehnberg, and Morken (1975).

Clinical observations except weight loss were difficult to correlate with exposure because many were not anticipated and were not recorded consistently. All the obvious ones were related to the respiratory system or the exposed nose and eyes. Epilation and dry desquamation were reversible. Nevertheless, serial pathology and hematology information indicated serious involvement of the hematopoietic system. While lung damage was the predominant injury in animals surviving more than thirty days, it was not the sole contributor.

These results led the authors to speculate on the validity of earlier conclusions that the important dose from immersion in an infinite cloud is entirely the external dose, at least with the soft beta particles of krypton. Depending upon skin characteristics, the lung or hematopoietic system might be injured as much as the skin. They suggested a need for infinite-cloud lethality studies to settle the issue, also to establish the possibility of skin tumors from chronic exposures. Some of this was taken up in the Plowshare program, which we shall examine later.

The Hanford work with ^{85}Kr began in fiscal year 1976 and has been reported upon in every annual report since. It included accumulation and tissue distribution in adult rats, dogs, and sheep, also in gravid rats and pregnant sheep, and finally, relatively long-term toxicity to both adult and embryo. Total body exposure of newborn rats was added to simulate external exposure from cloud passage.

The work on accumulation and tissue distribution began at quite low levels, comparable to the maximum permissible air concentration. The majority of tissues equilibrated quickly. Body fat and gastrointestinal tract were slower, requiring nearly four hours to reach equilibrium. There were some surprises in the desaturation curves. Gastrointestinal tract, which was slow to saturate, lost the krypton quite rapidly. The adrenal gland, which saturated quickly, retained the krypton for several hours.

Dose calculations were made for the rat (Willard and Balliou 1977a) for chronic exposures based on the kinetics determined in the acute four-hour exposures. Surprises are that the doses to adrenals, fat, ovaries, and pelt exceeded those to lungs, with contents of the large intestine close behind. On this basis, dosimetry based on ideas of more or less uniform accumulation and retention except for fat, as might be done without these biological data, could be considerably in error. On the other hand, the actual doses accruing from exposure at the $(\text{MPC})_a$, $(a) 3 \times 10^{-7} \mu\text{Ci } ^{85}\text{Kr}/\text{m}^3$, are exceedingly small. Both of these points are illustrated in table 10.1. Skin surface doses under these same conditions would be very much higher (e.g., rad per day).

In the same annual report, Willard and Ballou (1977b) compare retention kinetics in rat and dog. They were very similar with a short-lived component (5- to 7-min half-life) accounting for 40% to 45% of the activity and a longer-lived component (40- to 60-min half-life) accounting for the balance.

Later work (Willard et al. 1978) suggested three components for whole-body clearance in the dog (5-, 30-, and 100-min half-lives) and calculated radiation doses were in somewhat different order, although still quite low. These put lung at the top and adrenals fifth, but this is artificial since the lungs were full of the ^{85}Kr atmosphere at the time of sacrifice. The partition coefficients and calculated dose for chronic exposure are shown in table 10.2.

(a) $(\text{MPC})_a$ Maximum permissible concentration in air.

The accumulation and deposition of ^{85}Kr in pregnant animals indicated the same general behavior as in adults (Andrew, Sikov, and Willard 1977) except that, in general, the fetal tissue contents were lower than those of the adult (e.g., in sheep, see Andrew et al. 1978, figure 3.42). This was especially true of fetal versus adult fat. The authors do not speculate on what this might indicate regarding placental transfer of a noble gas like krypton.

The Hanford group, having established the pharmacokinetics to their satisfaction, turned to much higher exposure levels in order to determine effects. Again they looked at adults, newborn, and embryos. The most extensive experiment was chronic exposure of rats to air concentrations of 3×10^{-3} , 3×10^{-4} , and $3 \times 10^{-5} \mu\text{Ci}/\text{ml}$ for their life span. These are to be compared to the $(\text{MPC})_a$ of $3 \times 10^{-7} \mu\text{Ci}/\text{ml}$. The exposures started in June 1978. The highest air concentration yielded cumulative radiation doses for the first year of 2,000 rad to the skin, 22 rad to the lung from both the krypton incorporated in lung tissue and that in the airways, 5.2 rad to adrenals, 4.8 rad to fat, and less than 1 rad to all other tissues (Willard et al. 1979). This was reported on further in 1980, 1981, and 1982. Exposures were terminated for budgetary reasons at 808 days, but effects on survival were already well established by this time. The remaining animals were kept for life-span study.

Survival of the exposed groups was not significantly different from controls except for one anomaly, the middle-dose group. Malignant lesions were not significantly higher in any of the exposed groups, even skin tumors. Leukemia incidence was not notably different either (Willard, Tolley, and Ballou 1981; Ballou 1982). Ballou concluded that these results "attest the conservatism of the established limits for occupational and population exposure to ^{85}Kr " (Ballou 1982).

When newborn animals were exposed to concentrations producing skin doses of 850, 2,300, and 4,700 rad (Ballou and DeFord 1981), there were from 44% to 100% skin lesions and mortality from 33% to 80%. Follow-through on histopathology showed that newborn rats (two studies) developed skin carcinomas and leukemia after exposures at approximately 5.2, 12.7, and $25.9 \mu\text{Ci}/\text{ml}$ for six hours (Ballou 1982). The carcinoma incidence was dose related. The leukemias were too few to attempt dose-response correlations. The skin dose was approximately 958, 2,328, and 4,738 rad, respectively, at the three dosage levels.

By lack of mention, we must assume that skin lesions were not seen in the work at 10^2 , 10^3 , and 10^4 times the $(\text{MPC})_a$, just as life-span shortening and malignant tumors were not seen. The results thus tell us that (1) we are correct in considering skin the critical organ for ^{85}Kr exposure, and (2) the radiation doses from these noble gases required to produce lesions are at least as high, if not higher, than those associated with similar effects from x- or gamma-radiation.

The work at Brookhaven was done in the medical department and used sixteen human subjects (Susskind et al. 1977; Ellis et al. 1977). They inhaled a ^{79}Kr -air mixture from a spirometer system for about 10 min during which the concentration of ^{79}Kr was monitored by a detector at the mouthpiece and in the chest region by a wide-field gamma camera. After 10 min, the system was switched to room air, and the ^{79}Kr activity of the expired air and of the chest region was monitored continuously. This was called the "washout phase" and showed rapid clearance with half-times in two phases—a very rapid one of about 20 sec and a second one of about 4.7 min half-time. There was variability in these, especially the second phase, but it was not as large as mentioned in the Kirk-Morken work (standard deviation of ± 2.05 for the 4.74-min half-life).

After the initial "washout phase," the subjects went to the Brookhaven whole-body counter for a series of measurements extending out to as long as 55 hr. The characteristics of the Brookhaven counter allowed measurements out to quite low counts. There were at least three half-times that could be associated with this later period. The mean half-lives were 0.33, 2.41, and about 7 hr. A profile of the distribution in various parts of the body as a function of time could be drawn by putting the counter in a coincidence counting mode. This was seen in figure 10.2.

The half-time of the long-term component correlated highly with the percentage of total body fat and with half-times in the literature for adipose tissue. The profile (figure 10.2) also shows localization and longer retention in body regions of high fat content (upper thighs and lower abdomen). While the authors do not comment on the point, it would seem that this system would be useful in clinical measurements. By virtue of this work, the kinetics of krypton are well established in man.

Before we leave the noble gases, we should pause momentarily to recognize, as did Kirk (1972), that there are still unexplained phenomena regarding the biological effects of these elements. Most of them occur at high pressures. However, some, such as inhalation anesthesia in man, inhibition of the growth of fungi, etc., occur at partial pressures and total pressures consistent with normal physiological function (Buchheit, Schreiner, and Doeblner 1966). There have even been reports of radioprotection, as well as potentiation, with xenon and krypton (Markoe, Anigstein, and Schulz 1970).

On the whole, the experimental work has done little to controvert the conclusions drawn from the computational approach, but such was not expected. It has supported the general view that these elements present hazards of quite a different nature from the inhaled particles (Cohn, Ellis, and Susskind 1979). That this does not extend to all of the mobile gases we will see in subsequent sections.

B. Iodine Vapor

1. The Setting

The several isotopes of iodine are among the most abundant of the fission products. We have already noted that iodine was among the earliest of the radioactive materials to be discovered in the environs of the Hanford reactors and fuel processing plants. This was responsible for the large program with sheep that we reviewed in chapter 8. Ingestion was the route of administration chosen for that work since the principal problem appeared to be deposition of iodine vapor and salts therefrom on vegetation. This decision is probably correct for releases from routine operations, since the air concentrations would ordinarily not be high enough to present an inhalation hazard that was greater than the hazard from ingestion of accumulated depositions.

In the case of larger releases under accident situations, the air concentrations of the radioiodines might be quite high. Whether inhalation is or is not the controlling route of entry depends upon conditions.

For many years, health physicists, meteorologists, environmentalists, and regulators have sought to quantify the behavior of airborne effluents from reactor and fuel processing operations. Modeling was the predominant approach, although there were occasional field checks with known and controlled releases (chapter 14). Iodine releases occupy a prominent place in all such modeling.

The reader is referred to the three-volume proceedings of a Health Physics Society midyear topical symposium on reactor siting held at Idaho Falls, Idaho, in November 1970 (HPS 1971); also to an international symposium on fission product release and transport held at Oak Ridge in 1965 (ORNL 1965); and to the Air Cleaning Conferences and the Conferences on the Peaceful Uses of Atomic Energy referenced in chapter 9. These in turn were greatly expanded in the 1970s by the Reactor Hazard Evaluation Study ("Rasmussen Report," NRC 1975) and a host of environmental impact statements. We will have occasion to look at some of these in later chapters. For our present purposes, it is sufficient to review first the modeling approach and then the experimental data applicable to iodine vapor releases.

The widespread uses of iodine and iodinated compounds in clinical medicine has generated a tremendous literature. A sizeable portion concerns untoward, i.e., toxic, effects. However, iodine vapor is almost never considered to be the culprit in these situations. We will review these aspects when we consider the relationship of internal emitter toxicology to nuclear medicine in chapter 20.

2. Reactor and Related Hazards

There is no question that most of the iodine inventory in a power reactor would be in vapor form at the temperatures in the core and in the fuel rods; this is even more true in a serious loss-of-coolant accident (LOCA). However, the events subsequent to release can be quite variable.

First we should consider the cadre of iodine isotopes likely to be present in an operating reactor; most of them are depicted in table 10.3.

TABLE 10.3: Selected Iodine Isotopes

Mass Number	Half-Life	Direct Fission Yield, Percent	Yield from Fission Product Chains, Percent	E _{max} (β), MeV

Source: Modified from Holland 1963. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1963.

Quite obviously, only the isotopes 131 through 135 ^(a) are of importance as potential inhalation hazards. The earlier members have half-lives that are too long; the later members have half-lives that are too short. Quite obviously also, the decay rates of 132 through 135 leaves only 131 as a possible isotope to be reckoned with if there has been appreciable "cooling" of the reactor fuel before release of the iodine in, for example, fuel reprocessing or waste disposal. If the delay has been considerable, even 131 would be unimportant.

Lest we be lulled into complacency by the predominance of short half-lives among the iodine isotopes, we should recognize the enormous inventory of the iodines in a reactor core at "saturation," i.e., when equilibrium of generation and decay is reached. This is shown in table 10.4, taken from NCRP 1977. (These figures are comparable to the inventory calculated in the voluminous Reactor Safety Study begun by AEC and issued by the then-new Nuclear Regulatory Commission [NRC 1975].)

TABLE 10.4. Saturation Inventory of Iodine Isotopes in a Reactor Core^{a,b}

Isotope	Activity
	(Ci/MWt ^c) $\times 10^4$
131	2.5
132	3.8
133	5.6
134	6.6
135	5.1

^aFor the calculation of saturation activities see Appendix A.

^bThe values for the saturation inventory shown in this table are essentially the same as those calculated for the "Reactor Safety Study," WASH-1400 (NRC 1975), which appeared during the preparation of the final draft of the present report. The calculation of the values in the table involves ^{235}U thermal fission yields at constant power for three years with removal of radionuclides only by radioactive decay. The calculation of the values for the WASH-1400 report involves the ORIGEN code which is more realistic (including neutron absorption, three-region core, loss by neutron capture, Pu buildup, etc.). Since the maximum difference between the two results is <12 percent of these iodine nuclides, the values in this table are retained because these have been used to obtain the results on absorbed dose which appear in Appendix B. The results in Appendix B have been prepared especially for this report since no documentable reference is available in the literature.

^cMWt is megawatts thermal.

Even with materials of short half-life, this enormous inventory is sufficient to supply ample iodine vapor to pose inhalation and/or ingestion hazards in the event of a serious reactor accident (e.g., LOCA). Even lesser accidents and ones of a different type, such as the releases at the Windscale reactor in England in 1957, can be significant. It is estimated that 20,000 Ci of ^{131}I were released to the environment from this air-cooled and uncontained reactor (chapter 11).

(a) The long-lived 129 isotope will contribute significantly to the iodine content of the biosphere and cannot be neglected. However, it is most unlikely to be an inhalation hazard.

3. How Important is the Inhalation of Iodine Vapor?

As part of the first National Academy of Sciences National Research Council (NAS-NRC) review of fallout problems (the BEAR reports, i.e., Biological Effects of Atomic Radiation), much attention was directed to the thyroid. When the Federal Radiation Council (FRC) was organized (see chapter 16), it requested opinions from the NAS-NRC on pathological effects of thyroid irradiation. The report (FRC 1962) was focused on fallout from weapons testing and dismissed the absorption of ^{131}I by inhalation as unimportant "except possibly in fall-out intensities which are intolerable for other reasons" (p. 2).^(a) The food chain, especially milk, seemed the most important route. This was reiterated by Wehmann (1963) at Idaho Falls using the results of field releases of iodine and calculations therefrom.

The Rasmussen study of reactor safety (NRC 1975) concludes that the escape fraction of elemental iodine from reactor core material would be very large. It considers the reactivity of iodine vapor with many substances and the consequent production of iodides of different volatilities, including hydriodic acid. The study postulates that escape of from 50% to 100% of the iodine inventory can be expected with either a meltdown or "gap release." They took 90% as the probable value. Considering the size of the inventory, an acute inhalation hazard could easily exist were any large fraction to be released to the environment, whether it be 50%, 90%, or 100%. Thus, again the dismissal of inhaled iodine in the FRC report is found not to be universally correct.

The NCRP report already cited uses two models, a conservative and a realistic one. It calculates noble gas and iodine fractions available for release in a LOCA. They are estimated for both boiling water reactors (BWR) and pressurized water reactors (PWR). The iodine release fraction from the PWR is 25% on the conservative model, only 2% on the realistic model. For the BWR, equivalent figures are 25% and 0.04%. (It is not clear why these are so much lower than the releases calculated in the Rasmussen Report.) These fractions can be reduced considerably more by the presence of alkali sprays, filters, and other ways of entrapping iodine releases commonly installed in reactor containment buildings.

Absorbed doses to thyroid from ^{131}I – ^{135}I are calculated by the NCRP Committee for a variety of times after release and distances from the point of release. Maxima are 350 rad at the nearest point (0.5 mi) and longest time (720 hr after release) for the PWR and 1,700 rad for the BWR, both using the conservative model; 1,100 mrad for the PWR and 29 mrad for the BWR using the realistic model. Doses to other tissues are not mentioned because of the extraordinary ability of the thyroid to concentrate iodine and thus to receive most of the radiation dose. These calculations are for the *inhalation* route. Assumptions are made regarding breathing rates and the so-called " χ/Q " values (the concentration at a point of interest in Ci/m^3 relative to the release rate at the source in Ci/s). Thus, even though thyroid and not lung is the critical organ, the inhalation route can be the more important one in case of a large and relatively sudden release. The calculated absorbed dose due to external radiation from the cloud (plume) is from one to two orders of magnitude lower than the dose to thyroid. The importance of the external dose was thus found to be much less than in the case of the noble gases. The dose by ingestion was lower but would grow with time if contaminated food or water were consumed.

(a) The studies of the Marshallese (chapter 12) do not confirm this (Cohn 1982, personal interview).

Book (1980) has calculated thyroid doses as a function of age in the population and the mode of exposure, i.e., inhalation versus ingestion. He concludes that fetuses would receive the highest thyroid dose from radioisotopes of iodine inhaled by their mothers. Infants would receive the highest thyroid dose from radioiodines in milk. Under conditions of constant (and low) atmospheric concentrations, he calculates that the dose from milk would exceed that from inhalation. However, under conditions of a reactor accident, the dose from inhalation would be sizeable. The fetal thyroid dose from maternal inhalation is calculated as about ten times the dose to the adult thyroid.

The answer to our original question is thus, like so many scientific questions, "yes" and "no" depending on conditions of exposure, the release rate, the age of the recipient, etc. On balance, it must be concluded that inhalation of the iodines must be reckoned with, and relevant biomedical data must be at hand. Especially it must be remembered that the chemistry of iodine is quite complex, and production of volatile compounds may take place under situations where the iodine was considered to be "fixed." This may apply as much to laboratory and hospital situations as around nuclear facilities.^(a)

4. Names and Places

Before we visit the laboratories to review the experimental work on iodine vapor and closely related subjects, we should identify some of the people and their home institutions^(b) who were most involved in the dosimetric and other calculations we have just discussed:

5. Experimental Work with Iodine Vapor

The first major postwar symposium on biomedical work with iodine was held at Brookhaven National Laboratory in 1948. It did not have a single paper on iodine vapor (BNL 1948). They all concerned its use as a tracer or therapeutic agent, work that had gone on apace even during the war years. A second major, but less clinical, symposium was the second Hanford biology symposium held in 1962 (Bustad 1963). H. D. Bruner's introduction (Bruner 1963) to the proceedings tells the story of Hanford's very early concern with airborne iodine and the comprehensive and outstanding research program that grew out of it (chapter 8). Here the concerns lean heavily toward the problems of fallout and the release of iodine from nuclear facilities. Despite many reports concerning entry of iodine into biological systems and man's food, only two address the inhalation of iodine vapor directly. A third uses other routes as a surrogate for inhalation in sheep. The shift in emphasis among those concerned with internal emitter toxicology is very evident nevertheless.^(a)

In chapter 9, section IV A, work of Willard and Bair in 1958 was cited in which the behavior of iodine vapor and silver iodide particles was compared. In contrast to expectations of rapid lung clearance for the vapor and slow clearance for the insoluble iodide, it turned out that both cleared at about the same rate. Deposition favored the vapor by 70% versus 12%. This work started the realization that biological behavior on inhalation and solubility in water may bear little relation to each other. While the tissue distributions were different (figure 9.14), the results suggested that the "vapor" behaved more like a particle than was expected, and the particles behaved more like a vapor than expected. From this we can draw one of the first lessons to be gained from the experimental work—many of the situations for the respirable gases will be neither purely like the noble gases nor entirely like the inhalation of particles. In the instance of iodine, its high reactivity might quickly change the vapor state to a particulate state on inhalation.

(a) Many of the people concerned with the clinical aspects took part as well in this work.

At the 1963 Hanford symposium, Bair et al. (1963) followed up on the earlier work with inhaled iodine with a study aimed directly at the problems of releases from nuclear facilities and the idea of blocking uptake of radioiodine by stable iodine.^(a) They measured the effects of varying amounts of stable iodine (^{127}I) on the behavior of inhaled ^{131}I . Vapor of stable iodine was released from a separate generator located in a separate compartment of the usual apparatus and mixed with the radioiodine. However, it soon became evident that relatively large quantities of stable iodine would be required, and the method was not able to handle the amounts needed. Instead, a chemical generator was developed to release stable iodine and radioiodine together from a solution of sodium iodide. Less than 1% of the released iodine was associated with particles.

Both rats and dogs were used in the study, the dogs being exposed by the nose-only system to which they had been trained. Several hundred rats and four trained dogs were utilized. The amounts of ^{127}I ranged from 0 to 5,300 $\mu\text{g}/\text{l}$ in the inhaled air. The exposure concentrations of ^{131}I ranged from about 0.1 to about 6.5 $\mu\text{Ci}/\text{l}$. There was also an experiment that utilized a low iodine diet and one in which 100 mg of potassium iodine were given subcutaneously. The exposure concentrations for the dogs were lower (0.018 to 0.37 $\mu\text{Ci}/\text{l}$).

Full balance studies were done on tissues and excreta. As expected from the experience with iodine in clinical medicine, the primary route of excretion was urinary, and the rate was quite high. The results showed clearly that ^{131}I deposition in the thyroid could be much depressed by suitable additions of ^{127}I . Three graphs taken from the work with rats are given as figure 10.4A, B, and C. The first graph shows the uptake as a function of time. The second graph shows thyroid ^{131}I at forty hours as a function of the ratio $^{127}\text{I}/^{131}\text{I}$ in the inhaled air. A third graph (figure 10.4C) is a composite showing deposition of both isotopes in both rats and dogs.

The dilution of radioiodine vapor with stable iodine produced much less reduction in ^{131}I deposition in the dog than in the rat. It took up to 50 mg of stable iodine to reduce radioiodine deposition to one-half (an exposure concentration of 4.2 mg/l). The minimum lethal concentration of stable iodine is given as 14 to 18 mg/l. Hence, the maximal amount is uncomfortably close to the toxic dose. Obvious respiratory-tract irritation occurred at the higher levels, even in the rats. This impelled the use of subcutaneous injection for the highest doses of stable iodine.

This work, along with work using other routes of entry, helped to prove beyond doubt that stable iodine could greatly reduce uptake of radioiodine by the thyroid. Ideas have been bruited about of finding ways to add stable iodine to the off-gases in case of accidental discharges from nuclear facilities. However, the relative ineffectiveness seen in the dog and the large amounts needed discouraged this approach. Those concerned with planning turned to the idea of giving the stable iodine by mouth.

The NCRP report already cited (NCRP 1977) is directed primarily at the feasibility of having stocks of stable iodine both in the plants and in the near-to-site

(a) Many proposals had already been considered for adding stable iodine to dilute out the radioiodine as deposited in the thyroid. Most of these involve administration of stable iodine to the recipient and will be reviewed in chapter 19. A novel idea put forward by AEC Commissioner Wilson (Robert E. Wilson) was to have a large amount of stable iodine placed in the reactor itself in such a way that it would dilute the radioiodine in the gas stream in the event of an unplanned release.

FIGURE 10.4A. Thyroid uptake of ^{131}I in rats after inhalation of ^{131}I and ^{127}I . (Redrawn from Bair et al. 1963. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1963.)

environs of possible radioiodine release sources. Because of the many questions of differences among individuals as to the condition of their thyroid, their body iodine pool, potential for reactions to iodine (allergic), etc., the report stops short of making recommendations. It does describe the possibilities. It is understood that many plants do have stocks available for use on a voluntary basis and that some communities have done likewise.

The Lovelace group worked with ^{131}I given by inhalation or injection at very low, as well as more common levels. Thomas, Scott, and Chiffelle (1970) made a point to search for effects at levels ordinarily considered "tracer" levels in medical practice. The lowest infinite dose to thyroid was, however, 286 rad, which

FIGURE 10.4B. Relationship of thyroid ^{131}I to $^{127}\text{I}/^{131}\text{I}$ in inhaled air. (Redrawn from Bair et al. 1963. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1963.)

FIGURE 10.4C. Effect of ^{127}I deposition on thyroid ^{131}I and ^{127}I in rat and dog. (Redrawn from Bair et al. 1963. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1963.)

shows how difficult it is to produce a really low radiation dose to the thyroid when using radioiodine. There was some degree of biological change at all levels of dosage in this work.

There is ample evidence from the experimental work using other routes of administration that radioiodine can produce thyroid cancer, hypothyroidism, and thyroid nodules. There is no reason to expect anything different from inhaled iodine in sufficient quantity. The lowest doses in the long-term study with sheep at Hanford were low enough to be near the then maximum permissible dose rate to the thyroid. It took considerably more than this to produce thyroid tumors. We will have to assume the same relationships hold after inhalation.

Morgan, in a special editorial prepared for the 1963 Hanford iodine symposium, took a strong position on the use of the guides that had just been issued by the Federal Radiation Council. He was addressing primarily problems of fallout from nuclear tests, but the ideas apply as well to releases from nuclear facilities. He urges a strong and firm plan of action when iodine releases reach the top of Group III of the Radiation Protection Guides, viz., 10,000 μCi per day for any appreciable period. He stresses particularly the vulnerability of the young child and the fetal thyroid. Considerably lower figures would probably galvanize action today. We can conclude that there is strong contrast between toxicological importance of iodine releases as compared to the noble gases on the basis of both modeling and experimentation.

A whole new set of considerations has grown around the possible effects of certain organic compounds of iodine. Of particular interest are iodinated precursors of nucleic acids. These enter the cell nucleus and are incorporated into one of the basic components of living cells, DNA.^(a)

Similar considerations apply to compounds of tritium. We will review these in detail in connection with nuclear medicine, since that is where they have been used extensively. There is little chance of appreciable amounts of such compounds being produced after inhalation of iodine vapor.

IV. Tritium and Tritiated Water

A. Development of Interest

The existence of a radioactive isotope of hydrogen was announced in 1939 by Alvarez and Cornog (1939). It has a physical half-life of approximately 12.3 yr and decays by emission of a beta particle of very low energy ($E_{\text{max}} = 18 \text{ keV}$, $E = 5.7 \text{ keV}$) to ^3He . For convenience, it is frequently referred to by the symbol "T" rather than the more clumsy ^3H . We will use this nomenclature insofar as is convenient.^(b)

(a) Deoxyribonucleic acid.

(b) In geochemistry and some areas of environmental science, a special unit has been used to express tritium activity. This is the *Tritium Unit* (TU) or *Tritium Ratio* (TR). It was introduced by Libby and was sometimes called the Libby Unit. It represents the ratio of tritium to other hydrogen isotopes, usually in surface water. One TU is 1 tritium atom in 10^{18} atoms of the other hydrogen isotopes. This unit has not been used much in biomedical research, but it might be encountered in some of the environmental literature.

"Tritium is the most important and versatile radionuclide," (Evans 1966, 1974). If we consider its numerous tracer applications in chemistry, biochemistry, and physiology, this may well be true. In terms of radioisotope toxicology, it would have to have a lesser billing.

At room temperature, T combines with any gaseous hydrogen present to form HT. Even more readily, it supplants one hydrogen in any water vapor present to form "tritiated water," HTO, which is the most commonly encountered form of tritium in the environment. However, this reaction is far from instantaneous. Its rate depends on the presence or absence of various catalysts, the temperature, and many other factors. Fortunately, there is very ample literature in a form useful to the biomedical scientist on the reactions of tritium and tritiated water. Among these, special attention is directed to the review by Jacobs (1968) done as the first of the AEC Critical Review Series; the book by E. A. Evans of the United Kingdom Atomic Energy Authority (UKAEA) at Amersham and later the Radiochemical Centre at Amersham (Evans 1966, 1974); the first chapters of the 1979 NCRP report, *Tritium in the Environment* (NCRP 1979); the first sections of the tritium symposium sponsored by the EPA and held in Las Vegas, Nevada, in 1971 (Moghissi and Carter 1973); and the two-volume proceedings of a symposium in Vienna in 1961 sponsored by the International Atomic Energy Agency (IAEA 1962). A very useful and concise, but not easily available review, was written by Helen Woodard (1970) for the AEC's Health and Safety Laboratory.

Recently, in terms of the perspective of this book, the IAEA sponsored another symposium on tritium, this one nominally aimed at environmental problems and research (IAEA 1979). However, it provides also contemporary updating of data on man and monitoring methods. It was the result of a five-year coordinated research program sponsored by the IAEA and the Organization for Economic Cooperation and Development Nuclear Energy Agency, the U.S. Department of Energy (DOE), and Lawrence Livermore Laboratory, on behavior of tritium in various systems. The roster of papers in this volume shows very clearly the ubiquitous distribution of work on tritium both in the United States and abroad.

Willard Libby, who was for the chemistry and physical chemistry of tritium what Harold Urey was for deuterium, presented much of the early history of tritium as an introductory lecture to the EPA Las Vegas symposium (Libby 1973). He emphasized how improvements in instrumentation made it possible to detect the presence of the very low-energy beta particles from tritium. It is the presence of these very low energies that generated much of the biomedical interest, and generated also some unexpected problems as the research progressed.

In addition to the forms T, HT, and HTO, tritium is readily incorporated into organic compounds by exchange of T for H. The possible biological significance of these brought about a lively controversy. However, in this chapter we will consider T, HT, and HTO as respirable gases. The organic compounds are of less significance in this context than in tracer chemistry and nuclear medicine as they are for iodine. (Labeling of organic compounds does occur in the gas phase [IAEA 1962 Vol. II], but the reactions are slow. They require many days of constant exposure at moderately high partial pressures.)

The prewar tritium was, of course, produced by accelerators. Despite its immediate use as a tracer for studying water exchanges and pools in living organisms, there was not enough to pose a significant biological hazard. During World War II, it was recognized that tritium is produced in the fission process.

However, its great mobility and very low energy put it far behind most of the other fission products as one of the “new dimensions” we examined in chapter 6. The picture changed abruptly with the development of the hydrogen bomb and the fusion process, which requires the presence of tritium. Large quantities of tritium had to be produced, transported, and stored. It was the presence of these problems that led to the initiation of biomedical work on tritium metabolism and toxicology at Hanford—as reviewed in chapter 8.^(a) The need led to the construction of special reactors at Savannah River and a sophisticated research program.^(b) Further it was found that the fusion process produced and released much larger quantities of tritium than the fission process, and much of it was in the HT form. Consequently, much more tritium was present and releasable when the fuel was processed.^(c)

All of these increments added new dimensions in the early 1950s to tritium as a potential hazard as well as a very useful tracer and ingredient of the fusion process. We will review briefly some of the major sources of tritium and calculations of possible doses to humans, and then launch into the pertinent^(d) biomedical research at both the whole-organism and cellular level. Fortunately, there is an ample amount of such research. We will need to place less reliance on the computational approaches than we did in the case of the noble gases.

B. Source Terms and Calculations

Nearly everyone interested in tritium toxicology (as contrasted to its applications in physiology and biochemistry) has had a hand in developing estimates of the amount produced, present now, and likely to be produced. The laboratories most concerned with fallout problems and environmental impact statements have been the most active. The authors of the source-term work in the several compendia referenced in section III A present a good cross-section. So do the authors and institutions involved in the biomedical research.

We can use some rough and round numbers to illustrate tritium production rates and potential inventories, as gleaned from several sources:

- (a) A good perspective on the sudden growth of research on tritium, especially low-level releases to the environment, is given by Cohen and Higgins (1973) in the EPA tritium volume. A graph showing the number of publications on health implications of tritium and krypton shows tritium moving ahead startlingly from about 1958 on (1970 was the cutoff point). The authors discuss whether or not “the tritium problem” is all that serious. We will see here and in chapter 20 that it is the nuclear medicine aspect rather than the inhalation toxicology aspects that makes the largest difference in potential significance. Nevertheless, a very respectable literature has been developed around the toxicology of T, HT, and HTO.
- (b) Agnew (1982) very cogently points out that tritium production must continue at a rate that replaces approximately 10% of the U.S. stockpile every year simply to maintain the status quo. Unlike plutonium, tritium decays away. He points out the thirty-year age of the Savannah River reactors and their inefficiency and proposes that they should be replaced by new design systems, which could produce electric power along with the tritium. The design for such a system could be a very safe one.
- (c) Mason and Östlund (1979) from the University of Miami (Florida) estimate that the conversion of HT to HTO in the atmosphere is not rapid—“characteristic time” 6.8 yr, which, when combined with radiological decay, gives a half-time of 4.8 yr for HT in the atmosphere.
- (d) Pertinent to tritium and tritiated water as respirable gases.

Natural Tritium	World Inventory - about 70 megacuries
Weapons Tests (90% from fusion explosives)	Inventory - about 3,100 megacuries in 1963. Will decay to natural level by approximately the year 2030.
Nuclear Reactors	Production rate -
Light-Water Type	about 15 to 25 kilocuries per year per 1,000 megawatts electrical energy
Heavy-Water Type	about 600 kilocuries per year per 1,000 megawatts electrical
Liquid Metal Fast Breeder Type (Hypothetical)	about 30 to 60 kilocuries per year per 1,000 megawatts electrical
Production Plants	
Savannah River	about 200 kilocuries per year
Fuel Processing Plants	
Barnwell, South Carolina (Hypothetical)	about 700 kilocuries per year

It is less clear now than it was a few years ago by what number we should multiply the production rates from nuclear reactors. A little over a decade ago, it was projected that nuclear power might account for 430,000 MWe in the United States by 1990 (Unruh 1970b). It is now clear that this is an overestimate.

The figures above reflect actual inventory in only two cases—natural tritium production by nuclear reactions in the stratosphere and weapons tests. The others are only potential in terms of airborne inventory, since the fractions released need to be factored in. The release rates are very idiosyncratic to the installation and activity. In normal operations, except for weapons tests in the atmosphere, only a few percent of the amounts present would be expected to ever reach air, water, or food.

Quite clearly, the contribution of weapons tests has been and is expected to remain for a long time the primary source of tritium in the environment. It is, therefore, instructive to look at the radiation doses to man projected from fallout and nuclear power to the year 2000. (The estimate from nuclear power probably exceeds what will actually occur.) This is shown in figure 10.5.

FIGURE 10.5. Projected tissue dose rate from tritium in man. (Redrawn from NCRP 1979. Reprinted with permission of the National Council on Radiation Protection and Measurements, Bethesda, Maryland, copyright 1979.)

As we saw with the noble gases and iodine, the apparently huge inventory results in a yearly (average) dose to man in fractions of a millirad per year. Indeed, the curve seems to be leveling off at around 0.013 mrad per year.

Does this apparently minuscule figure mean we can forget about tritium and consider more important radionuclides? Hardly! These are average doses to the total population based on many assumptions regarding release rates, transfer, metabolism, etc. Individual doses in the vicinity of a facility under accident conditions or even routine exposures close-in can be entirely different.

There are also occupational exposures to tritium. In addition to those possible around the production plants, reprocessing facilities, etc., there is the luminous paint industry. As the saga of the radium dial painters unfolded (chapter 1), the watch and clock makers gradually turned away from radium.^(a) As we saw in chapter 8, they turned briefly to strontium as a substitute radioactive material to activate the phosphors. Later they embraced tritium as a better and safer substitute.

A book prepared by Moghissi and Carter under the aegis of the Bureau of Radiological Health of the U.S. Food and Drug Administration tells the story (Moghissi and Carter 1975). Also a careful field study by Bradley, Blais, and Jones (1971) gives much information resulting from surveys of the watch industry in the New York metropolitan area. It was in the watch industry of Switzerland where two cases of fatal exposure to tritium occurred. A survey of tritium pollution and the amounts of tritium handled in the Swiss industry is given by Krejčí and Zeller (1979).

The result of all of this is that we must know about the biological behavior of tritium. We cannot do a credible hazard evaluation without it. Fortunately (and furthermore), many facets of the biomedical research have great inherent scientific interest with a bearing on all of physiology, biophysics, and toxicology.

C. Biomedical Research with Tritium at the Whole-Animal Level

1. Uptake, Distribution, and Excretion

In chapter 8, we reviewed briefly the early postwar work with animals at Hanford done primarily by Thompson and Ballou. This work concentrated on metabolic turnover of tritium as a tracer in mouse and rat, and comparison to deuterium. It quickly established that absorption was very rapid, distribution to the tissues likewise rapid, and elimination, while grossly rapid, exhibited also some slower phases. These latter were taken to represent elimination from compounds that had bound tritium. In other words, T and HTO resided primarily in body water, but small amounts were bound into organic compounds. Most of this work did not utilize the inhalation route.

As part of the Hanford effort on tritium, Harry Kornberg, manager of the biology department, decided there was no alternative to determining the behavior of tritium in man. This was in the early 1950s. Because of the important role Hanford was playing in the development of the fusion process, security classification, even of biological work, was high. The Hanford and Los Alamos work, which we will review presently, proceeded more or less independently at the time.

(a) The conversion was not complete. Radium is still used some for clock dials, but not for watches.

Anecdotes are best when recalled by the participants. Therefore, I will quote liberally about this effort from a letter from, and interview with, Dr. Kornberg (Kornberg 1982a,b).

Early in the 1950s . . . Hanford manufactured tritium for the yet-to-be-tested fusion bomb. Workers on the production line, isolating and concentrating tritium in hoods and wearing fresh air masks, would suddenly show tritium in their urines after a minor mishap in the process. How were the workers contaminated? I was asked. My first guess was that the fresh air masks were defective and tritium leaked in.

It seemed reasonable that tritiated water should be absorbed readily from the lungs. Dr. Kornberg developed a model that predicted that it should be. However, he wanted direct evidence. Indeed, he did not really believe in the model's prediction that 98% of the HTO would be absorbed. The first experiment went as follows:

With the help of one or two members of the Biology Laboratory, I inhaled a measured amount and concentration of tritium oxide vapor and air from a rubber hot water bag attached to some laboratory tubing. After inhaling the liter of gas in one "normal" breath, I went about my regular duties. As I would do again later, I measured tritium in my urine for about a month. However, to make sure we found how much tritium oxide was absorbed right after I inhaled the vapor, I measured it in my blood first . . . I believed it important to get blood samples very soon after the inhalation—before I exhaled significant tritium and my kidneys transferred it from blood to urine.

The blood analyses showed virtually all of the tritium oxide inhaled absorbed!

Kornberg felt he had proven the point as to how the tritium was contaminating the workers, but the industrial hygienist did not think the mask leaks were sufficient. He postulated skin absorption played a role arguing from the passage of water through the skin. An experiment on anesthetized rat skin indicated possible absorption. Kornberg continues:

I decided we needed to know human skin absorption. So I flowed tritium oxide vapor in air over the skin on my forearm for a measured time, using the same size funnel we used on the rats, and then measured the tritium in my urine with time. This gave me some human skin and additional half-time data. But it was my skin, and it may not have represented normal humans'. I needed more volunteers.

One of them was my good friend, Carl Gammertsfelder, head of the Health Physics Division in the HI Divisions. I placed the funnel on his arm and flowed tritium oxide over it at a concentration and for a time calculated to give him no more than a fraction of the MPL of skin dose or body burden. For a week he turned over to me all his urine, which we analyzed for tritium to calculate skin absorption and body tritium half time. His data were much the same as mine, but something happened.

About a week after the exposure, at a staff meeting in Herb Parker's^(a) office, Carl showed me his forearm. On it was a 3 cm circular area (the size of the funnel) red, inflamed, scabbing, and ugly. I couldn't believe what I saw. I showed Carl my calculations. The exposure was safe! He nodded, smiled, and again showed me his forearm. Herb Parker glared at me.

That night I recalculated again. The dose was safe. What's with the arm?

The next day I saw Carl, and examined his arm. Now I saw. He had used Jean's (his wife) rouge and fingernail polish, he admitted, with glee. Herb was in on it.

(a) Herbert Parker, manager of the Radiological Sciences Department.

The final, and most difficult experiment was one to test skin absorption in a whole man, with no component of inhalation. Kornberg's description follows.

I decided that the only way to get a firm figure on skin absorption would be to expose the entire body of a volunteer, and that I would be the volunteer.

As if made to order, there existed in 100-F area a large box, made of panes of heavy glass. The original use of the big hollow glass cube, measuring about five feet on each edge, remains unknown to me. But it had a crawl-through doorway (which sealed) and some convenient ports. It looked ideal. We had it transported to the laboratory's loading dock, scrubbed it thoroughly, fitted it with appropriate tubes and samplers, and calculated the concentration of tritium oxide needed inside the glass box to give the volunteer who was to sit in the box for one hour a large enough fraction of the permissible body burden to ensure accurate tritium measurements in the body water.

One Saturday morning when the plant was empty of people . . . Chester deLong and I met at the laboratory to set up the experiment. We introduced the tritium oxide and waited until we felt it was well mixed with the box's air by the electric fan we had put in the box. There were two tubes loosely attached to the stool the volunteer was to sit on, ends of which were fitted with one-way valves and protected against contamination. The other ends of both tubes were outside the box. One, the exhaled air tube, simply exhausted into the laboratory air. The other was attached to the laboratory's pressurized air supply through a flask containing cotton to clean the laboratory air to sustain the volunteer.

When all was ready, I removed all my clothes except my shorts, took a deep breath, held it and quickly opened the door and entered the box, closing and latching it behind me. Still holding my breath, I removed the protective covers from the ends of the two tubes, put them in my mouth and tried to inhale. I barely could. Not enough air was coming through! Either I had to get more air through the intake tube or inhale the tritium-oxide-laden air in the box. If I did the latter, I would spoil the experiment for at least a couple of weeks, until most of the inhaled tritium cleared my body water. Frantically I waved one hand up, up repeatedly while the other pointed to the intake tube. Chet deLong, standing just outside the box, understood immediately and ran to the bench in the neighboring laboratory to increase the air. Now so much air came through I momentarily felt like a balloon. Rather than letting the excess air escape and dilute the tritium atmosphere, I breathed rapidly until Chet got back. I motioned for him to turn down the air a bit, which he did, and the valve in the exhaust tube was now able to handle the surplus air.

After an hour the timer rang and I climbed out of the box, took a shower and dressed. For at least the next month I measured the volume of urine excreted and gave samples to Biology's analytical laboratory. The results supported and gave credence to our findings using small areas of skin: The rate of tritium oxide absorption through the skin was the same as tritium oxide absorption via inhalation, at least in my case. Since I then weighed about the same as a "standard man," our data were used for radiation protection procedures among tritium workers at Hanford. (Kornberg 1982a)

The conclusion that skin absorption of HTO is essentially equal to lung absorption has held up to this day.^(a)

At about the same time as the Hanford work with animals described in chapter 8 and the above-described experiments on man, the Los Alamos Scientific Laboratory began biological work with tritium. As a weapons laboratory, Los

(a) The reports of this work were eventually declassified, some of it published in part. But it did not receive the attention it deserved because others had already reported the same thing in open literature publications.

Alamos had ample opportunity to encounter practical problems with tritium exposure. Furthermore, they had in their midst an expert on the physiology of water exchange and water balance, viz., E. A. Pinson, an Air Force Officer assigned to the laboratory. We reviewed the essence of their findings and saw Dr. Pinson's background when we discussed the basic Los Alamos postwar work in chapter 8.^(a) A small segment of the work involved inhalation of T and HTO in the vapor phase.

The now classic review by Pinson and Langham (1957) included the finding, developed earlier at Hanford but not reported immediately, that man absorbs 98% to 99% of the tritium activity when HTO vapor is inhaled. Blood content rose sharply and declined by first-order kinetics with a half-life of about 12 min. Half-time in the body averaged 11.5 days. This work also showed that HTO is absorbed readily through the skin. At equal vapor pressures, HTO passed inward at a rate comparable to that of the insensible perspiration moving out. As Kornberg found, the lung and skin contributed approximately equally to the uptake. Clothing retarded the skin uptake temporarily, but only water-impermeable clothing could prevent the skin absorption.^(b) It was confirmed that any permissible concentrations in air, based on lung uptake, should be halved to account for the skin absorption. (Woodard [1970] raised the question of why the rates should be approximately equal for lung and skin when the alveolar surface area in lung is about fifty times the surface area of the skin. She offers as explanation the fact that the lung surfaces are bathed in fluid and the specific activity of water absorbed is thus less than when HTO enters from the dry skin.)

The work of Pinson and Langham also involved inhalation of T. Very much less is absorbed, on the order of only 0.1%. The inhaled T is gradually converted to HTO, about fifty times more rapidly by the mouse than by man. Absorption and conversion figures were calculated from the amounts in urine.^(c) Figure 10.6 illustrates the contrast in absorption of the two forms of tritium as measured by excretion rates.

Note the large difference in inhaled gas concentration between HT and HTO. The very large difference in absorption of HT versus HTO can be illustrated by noting that equal rates of absorption would occur if HT were inhaled at a specific activity 1,500 times that of HTO. The factor becomes 15,000 for equal rates of appearance of tritium in the body fluids. Thus, most of the tritium of biological significance as a respirable gas is HTO rather than HT.^(d)

Elimination occurred first as tritiated water vapor in the expired air or as T or HT exhaled from the lungs unchanged. This process was very fast and represented essentially the immediate washout. Longer-term excretion after inhalation was slower but still relatively rapid, viz., a quick component with $T_{1/2}$ of about five minutes and a slower component with $T_{1/2}$ about twenty minutes in man (Pinson and Langham, 1957, figure 9). Other half-lives appeared in both

(a) It should be added that Pinson started the ball rolling with a definitive review of deuterium and tritium as tools for water exchange studies (Pinson 1952).

(b) This finding was not a part of the Pinson-Langham work.

(c) It has been demonstrated that the bacteria in the gastrointestinal tract are probably primarily responsible for the oxidation *in vivo* of HT to HTO (see Pinson and Langham).

(d) Since monitoring devices cannot distinguish between HT and HTO, it is customary to assume that any airborne tritium is in the form of HTO. In moist air, T or HT are converted to HTO anyway, but not very rapidly in the absence of catalysts.

FIGURE 10.6. Tritium activity (as HTO) in urine of rats during inhalation of an atmosphere containing HT or HTO. (Redrawn from Pinson and Langham 1957. Reprinted with permission of the American Physiological Society, Bethesda, Maryland, copyright 1957.)

mouse and man, and a fairly considerable variability appears to be common both among individuals and in the same individual at different times. (Remember we saw this phenomenon also with the noble gases. It may reflect the ease with which physiological and environmental conditions can influence these rates.)

Meanwhile, at the Savannah River plant of the AEC and in other studies on man, this same variability was also noted (Butler 1962; Wylie, Bigler, and Grove 1963; Butler and LeRoy 1965; Sanders and Reinig 1968). This was occupational exposure at low levels in general and included over three hundred individuals. Average excretion half-lives varied from twenty-four to eighteen days. Reasons for the variability were easily forthcoming, e.g., forced fluid diuresis, high versus low ambient temperatures, etc.

The excretion data reported from Savannah River showed fairly clearly a three-component exponential relationship to time with half-lives of 6.14, 23.4, and 344 days. The original data and the breakdown according to a three-component model are shown in figure 10.7A and B, taken from Sanders and Reinig (1968).

In a couple of accident cases with higher HTO intake (86 and 46 mCi), the third component was clearly detected in the urinary excretion rates. This had a half-life of several hundred days and may represent the reincorporation of free water tritium released by breakdown of previously incorporated amounts (Woodard 1970).

Toward the end of the Los Alamos work discussed above, the Berkeley group re-entered the picture. Their point of view was primarily the study of exchange phenomena, and they used intravenous or oral administration of HTO. Siri and Evers (1962) worked with rats, pigeons, guinea pigs, and rabbits in which tissue contents were measured directly. This was followed by indirect estimates in man. They concluded that about 0.9 of the exchange occurred with a half-time of one hour while the remaining 0.1 of the exchange had a half-time of ten

FIGURE 10.7A. The observed concentrations of tritium in urine and the least-squares fit of the data. The equation of the line is $U(t) = 742e^{-at} + 2.06e^{-bt} + 0.034e^{-ct}$.

$$a = \frac{0.693}{6.14} \text{ days}^{-1},$$

$$b = \frac{0.693}{23.4} \text{ days}^{-1}, \text{ and}$$

$$c = \frac{0.693}{344} \text{ days}^{-1}.$$

Assuming that all the tritium was initially in the body water, the percent remaining at any time after exposure was obtained by normalizing the above equation to 100 at $t=1$. Thus, $X(t) = 94.72e^{-at} + 0.2776e^{-bt} + 0.004570e^{-ct}$. (Redrawn from Sanders and Reinig 1968.)

FIGURE 10.7B. The percentage of assimilated tritium in compartments A, B, and C as calculated by an absorbing Markov chain. Curve A represents tritium in body water. Curves B and C represent organic-bound tritium. Curve A + B + C represents total body tritium. Curve X is the percentage of absorbed tritium in body water. (Redrawn from Sanders and Reinig 1968.)

hours. There was a difference between the "tritium space" and total body water determined by desiccation of about 1.5% to 3.5%. In man, the exchange was estimated by concurrent measurements of tritium and antipyrine spaces.^(a) The difference was about 2% and may represent tightly bound tritium.

(a) The drug, antipyrine, is distributed almost entirely in body water.

Results after injection with long periods of observation point to three components in both man and rodents (three, ten, and seventy days in rat and mouse; eight, ten, and four-hundred days in man). The long time components point to some incorporation of T in body tissues.

Snyder et al. (1968) report on excretion rates and calculate doses in the case of an Oak Ridge employee who inhaled HTO.^(a) The excretion could be represented by the same two exponential equations with time terms equivalent to half-lives of nine and about thirty-four days. It is not clear if this case involved enough tritium to detect a third long-term component. On the basis of a two-compartment model developed from these excretion data, Snyder et al. calculate a total dose to the body water. The authors make no comment on the possible reasons they saw two rather than three compartments.

In further experimental work at Los Alamos, Richmond, Langham, and Trujillo (1962) put tritium into their ongoing study of the comparative metabolism of radionuclides by mammals. The intake route was via HTO given intraperitoneally, intravenously, or orally, but it seems likely that the results would apply also to inhalation of HTO, although perhaps not inhalation of HT. Seven species were studied as shown in table 10.5.

TABLE 10.5. Los Alamos Species Correlation Experiment with Tritiated Water

Volume and Turnover of Body Water in Seven Mammalian Species							
Species	Sex	Weight (gm)	Dose (mc)	Route of administration	Exchangeable Body Water (% of body wt.)	Half-time (days)	Water Loss ¹ (ml/day)
Mouse	F	21.4 (24) ³	0.708	I.P.	58.49 ± 3.97 ² (24)	1.13 ± 0.14 (12)	7.22 ± 1.15 (12)
Rat	M	298 (12)	4.329	I.P.	59.61 ± 4.04 (11)	3.53 ± 0.40 (12)	34.54 ± 4.90 (11)
Dipodomys ⁴	F,M	93 (20)	0.850	I.P.	62.20 ± 2.35 (20)	11.82 ± 2.96 (10)	3.75 ± 0.95 (10)
Rabbit	F	3.159 (4)	7.100	I.P.	58.35 ± 5.31 (4)	3.87 ± 0.21 (4)	338 ± 62 (4)
Dog	M	10,582 (5)	1.270	Oral	65.95 ± 1.42 (5)	5.14 ± 0.18 (5)	946 ± 124 (5)
Man	F,M	67,302 (5)	2.000	Oral	55.34 ± 5.31 (5)	9.46 ± 0.88 (5)	2,747 ± 519 (5)
Horse	M	398,533 (3)	142.1	I.V.	65.71 ± 0.72 (3)	8.41 ± 0.53 (3)	21,722 ± 3,247 (3)

¹ From the derivative of $V_t = V_0 e^{-kt}$, when V_0 is the volume of exchangeable body water (ml), t is time O , and k is the rate constant of the exponential function (fractional change per day).

$$^2 \bar{x} \pm \sqrt{\frac{(x - \bar{x})^2}{n - 1}}$$

³ Number in parentheses is the number of animals composing the average.

⁴ Kangaroo rats; maintained in laboratory during experiment on dry pearled barley alone. No other sources of exogenous water were available.

(a) Some of the material may have been ingested. The dose is not known.

The average half-times were within a range from 1.1 days in the mouse to 9.5 days in man, a relatively constant value when the different water loss rates are compared. The kangaroo rat had the longest half-time, about 12 days, which is consistent with its adaptation to desert habitats.

The primary purpose of this study was calculation of daily turnover of exchangeable body water for each species. A correlation between daily water turnover and species weight was established. This has power function characteristics as shown in figure 10.8A. If the correlation is made with body solids rather than body weight, the kangaroo rat comes into line as seen in figure 10.8B.

FIGURE 10.8A. Inter-species correlation between log daily water loss and log body weight. (*Dipodomys* = kangaroo rat.) (Redrawn from Richmond, Langham, and Trujillo 1962. Reprinted with permission of Alan R. Liss, Inc., New York, copyright 1962.)

FIGURE 10.8B. Inter-species correlation between log body water content and log body solids content. (Redrawn from Richmond, Langham, and Trujillo 1962. Reprinted with permission of Alan R. Liss, Inc., New York, copyright 1962.)

This information using tritium as a tracer for determining body water has much intrinsic physiological interest. The coefficient of correlation between the two variables in figure 10.8A is 0.985, and the body water turnover is proportional to the 0.80 power of body weight except for the desert rat. From figure 10.8B it can be deduced that the relative partition of water and solids in adult mammals is constant with a value of 1 among the species.

These can be correlated with much earlier work done without radioactive tracers by Adolph (1943). He found a correlation between rate of water intake and body weight of fourteen species ranging from mice to elephants with a power function exponent of 0.88. Urinary output correlated with body weight with a power function exponent of 0.82.

This information has a direct bearing on dose calculations, should such be required for species other than man. Application to maximum permissible concentrations in water is laid out by Richmond, Furchner, and Langham (1960).

The Canadians were especially interested in tritium metabolism because of the large amounts (as much as 300,000 Ci/yr) of tritium produced in their reactors by neutron bombardment of the heavy water (deuterium) moderator. Osborne, at the Chalk River installation, measured absorption of tritiated water vapor in man (Osborne 1979). In work done in the early 1960s, he used volunteers in a chamber so that absorption was through both lungs and skin. The tritium in air concentrations ranged from 0.5 to 50 $\mu\text{Ci}/\ell$, and the exposures lasted from 1.5 to 60 min. The chamber contained HTO introduced by bubbling dried air through a container of tritiated water. In some runs, the subjects wore respiratory protective equipment; in others they did not. Intake rates were around 15 $\mu\text{Ci}/\text{min}$ per $\mu\text{Ci}/\ell$ in the chamber for unprotected subjects and averaged 9.6 for skin. Clothing further reduced the intake rates, but not by very much. Cotton overalls produced a relatively small reduction. It took special protective clothing such as the "PVC" suit to attain real protection as pointed out earlier.

Elimination half-lives in these experiments were 6.4 days for the shorter and 14.4 days for the longer component.

Tritium entering by inhalation or any other route follows body water grossly. Any incorporation into tissue constituents is not uniform. The glycogen and lipid of liver are notably high, and synthesis into reaction components of the glycolytic pathway and the base moieties of DNA has been established by work in a number of laboratories.

Work stimulated directly by nuclear energy problems took place at the Lawrence Livermore Laboratory and was published by Hatch and Mazrimas (1971). This established clearly the incorporation of tritium into many important biomolecules and confirmed the notion first enunciated by Thompson's work at Hanford (see chapter 8) that there is a static component in cells and tissues existing beside the dynamic component so dramatically demonstrated in the earlier years of tracer chemistry.

To accomplish this labeling, parenteral administration is preferred, and many of the experiments have been long-term ones with chronic exposure. The process probably has little significance for inhaled HT or HTO because of the high concentrations that would need to be inhaled over long periods.

As we saw, absorption of tritium through the skin is an integral part of exposure to the gas (T or HT) or tritiated water (HTO). The EPA laboratories at Las Vegas and Montgomery became interested in the skin absorption of various tritiated compounds, especially the many compounds used in luminous paints.

Skin absorption of these was in general lower than HTO (Kaufman et al. 1971; Wawerna 1973). The different compounds behaved differently in terms of skin absorption and probably would also on inhalation.

The work on absorption, distribution, and excretion was the basis for many dosimetric models with varying numbers of compartments. These are well documented in the NCRP report, *Tritium in the Environment* (NCRP 1979), and in the review by Woodard (1970), but can be found also in most of the monographs on tritium. Compartments postulated are body free-water tritium (BFWT), tissue free-water tritium (TFWT), and tissue-combined tritium (TCT). Calculations of integral exposure from TFWT and TCT in microcurie days per kilogram and cumulative radiation dose in rad have been done (e.g., Woodard 1970). A notable feature is the relatively low dose developed from, for example, a single intake of 1 mCi of HTO per kilogram of Standard Man, viz., only 17 rad in two thousand days.

A final rundown (for our purposes) on the kinetics of tritium in man is available in the IAEA 1978 symposium already cited (IAEA 1979):

1. Moghissi, by that time with EPA in Washington, gave biological half-lives of tritium in two former dial painters at surprisingly long times; 340 and 630 days, respectively.
2. Osborne, from Chalk River, Canada, gave new estimated values for skin permeation (not very different from earlier values).
3. Krejčí and Zeller from Radium-Chémie, Ltd., Teufen, Switzerland, told the story of tritium in the Swiss luminous compound industry.
4. Soldat and Baker from Battelle, Pacific Northwest Laboratories calculated worldwide dose from tritium releases from nuclear facilities.
5. The doses to humans were also presented by Eisenbud et al. as a summary of the NCRP report, *Tritium in the Environment* (NCRP 1979). (Authors were Eisenbud, New York University; Bennett, Environmental Measurements Laboratory; Blanco, Compere, and Jacobs, Oak Ridge; Goldberg, Scripps Institution of Oceanography; Koranda, Lawrence Livermore; Moghissi, EPA; Rust, University of Chicago; and Soldat, Battelle, Pacific Northwest Laboratories.)

As part of the rather extensive program on tritium effects mounted at Brookhaven (see next section), Commerford, Carsten, and Cronkite (1977) looked at the distribution of tritium in important biological molecules such as glycogen, hemoglobin, and chromatin. The tritium was given to mice in their drinking water, but, as noted earlier, we would expect similar behavior after inhalation. The exposures started at conception and continued throughout the lives of the animals. The specific activity of hemoglobin was lower than that of the tissue water (more was in heme than in globin) while the activity in chromatin was close to, but always somewhat below, that of tissue water. The specific activity of the carbon-bound hydrogen in glycogen was about half that in tissue water. The authors concluded that, on chronic exposure, the radiation dose to cell nuclei comes more from tritium present in water than from tritium bound to chromatin. Species differences in tritium metabolism led to the conclusion that humans would incorporate less tritium than similarly exposed mice. This has pertinence to inhalation exposure, drinking water exposure, and tritium in nuclear medicine (chapter 20). Estimates of oocyte uptake of deuterium as a surrogate for tritium were also made at Brookhaven (Slatkin et al. 1979).

2. Toxicology of Tritium as a Respirable Gas

a. Acute Toxicity

The generalization that tritium is one of the least toxic of radioisotopes has been confirmed in a general way by the postwar experimental work. Nevertheless, significant radiation hazard problems can exist if tritium is not handled properly. First, there are very large quantities around. Second, it is not easy to separate tritium from water, and large volumes may therefore be possible. Third, the skin absorption route may be forgotten. With these caveats, let us look at some of the aspects of tritium toxicology most pertinent to its intake in gaseous form.

First we should dispel the unfounded statement, which appeared early in the use of tritium, that one breath of tritium gas would be quickly fatal. What was in mind, of course, was a sudden large leak from, for example, a cylinder containing tritium gas. The idea was that the radiation would inflict irreversible damage to the respiratory tract. What was forgotten, of course, was the relatively long physical half-life of tritium and its relatively short biological half-life. Only a small fraction of the inhaled tritium atoms would decay in the lung. A 10-sec exposure to pure tritium gas would result in a dose of only about 6 rem (Evans 1974) and 10 min in a small laboratory room at 10% T in air would yield 40 rem. Furthermore, anyone in a position to receive a lung full of pure or even somewhat diluted tritium gas would be in greater jeopardy from oxygen lack than from the radiation dose. Having disposed of this somewhat hysterical scenario, let us examine the toxicological work.

Anderson and Langham at Los Alamos (1954) made an early estimate of tritium toxicology and concluded, as we might expect from the absorption figures just reviewed, that the hazard from T or HT is about 1/1,000 that from HTO, and the greatest danger from an acute exposure to a mixture of tritium gas in air is ignition of the explosive mixture!

Brues and colleagues at Argonne National Laboratory did one of the earliest experimental determinations of the toxicity of tritium as HTO in a mammalian species (Brues, Stroud, and Reitz 1952). They had been impressed by the many predictions of low toxicity and decided it was time for an experimental test. In addition, they were interested in the possibilities for special effects by selective localization of tritium compounds in cellular structures. They gave HTO intraperitoneally in saline solution to mice. In general, the results upheld the predictions of low toxicity. The thirty-day median lethal dose to the CF1 female mice was about 1 mCi per gram body weight. Calculation of the associated radiation doses indicated no special effectiveness of HTO in comparison to x rays, at least for acute effects.

Furchner (1957), at Los Alamos, whose ingenious approach to dose patterns we saw in chapter 8, did a similar experiment with similar results. Earlier, Anderson et al., also at Los Alamos, determined the LD_{50}^{30} for inhaled HTO to be about 1.5 mCi/ml of body water, which agrees well with the figures obtained with injected HTO.

The pathology in these cases was very unspecific. The effects were similar to acute radiation sickness seen after exposure to x rays or other low-LET external radiation sources.

Meanwhile, the work in man as well as rodents at from 1/100 to 1/1,000 of the LD_{50}^{30} was consistently showing no measurable changes for periods up to as long as two years.

b. Chronic Aspects

Luminizers. The evidence that tritium was not totally innocuous came with jarring impact from the experience with radioluminizers in Switzerland already alluded to (Seelentag 1973). Two fatalities came in workers who had handled from one hundred to several thousand curies of tritium activity over periods from three to six years. They used both the gas and tritiated water. The deaths were due to damage to the hematopoietic system, with symptoms referable to lung damage. For reasons that are not clear, changes in the white cells were much less marked than the decrease in numbers of red cells, as well as hemoglobin, (hyperchromic anemia). The authors classified the disorder as "aplastic panmyelocytopenia."

Monitoring methods for tritium were only under development in the early years of these exposures. Hence, estimation of exposure is difficult. The personnel wore film badges, but readings from these would be essentially worthless. Urine sampling gave the best estimates of dose.^(a) These and some estimates of exposure made before the urinary measurements started gave an overall whole-body dose of about 290 rem. This is for Case 1, an individual who steadfastly refused medical treatment for his developing symptoms. Obviously, the dose to bone marrow must have been much higher. The presence of pulmonary symptoms points also to inhalation as the route of entry for at least some of the tritium. There were two or three other individuals in the same installation who showed symptoms, but they did not progress.

The second fatality occurred in a different installation—one that had used ^{226}Ra and ^{90}Sr before tritium. The fatal case was the person in charge of production for many years. Others were seriously affected in this installation also. The total body dose for this second case was estimated at "less than 1,000 rem within three years."

As part of the elaborate study done by Seelentag, it was estimated that between 10% and 20% of the body tritium was bound in organic molecules, a much higher figure than the 2% or so deduced from acute exposures.

Experimental Work on Chronic Aspects. A substantial amount of experimental work has been done on the long-term effects of tritium exposure, including low levels. Four laboratories may be singled out for their willingness to look into long-term effects of this "innocuous" element: Brookhaven, Lawrence Livermore Laboratory, Los Alamos, and a couplet of Rochester and the EPA Research Center in Research Triangle Park in North Carolina. The Brookhaven work concerns both tritium in nucleic acid precursors (see chapter 20) and tritium entering through drinking water. The Livermore work involves primarily determinations of relative biological effectiveness (RBE) and will be discussed in a separate section of this chapter. The Rochester-EPA work represents essentially a career activity of one man, Daniel F. Cahill, and will be taken up as an entity here followed by the Brookhaven and Los Alamos work.

There is much similarity between the setting and development of Cahill's work with tritium and that of William P. Kirk with krypton, discussed earlier in this chapter. Like Kirk, Cahill was a Public Health Service officer assigned to Rochester for Ph.D. work. He came about five years before Kirk. He, too, chose to work in an area of developing interest to the Public Health Service and of much intrinsic interest.

(a) Excretion of tritium by workers preparing labeled compounds in Czechoslovakia has been reported by Houšková et al. (1973).

After an assignment at the Headquarters of the Bureau of Radiological Health, he went on to the EPA National Environmental Research Center in North Carolina. The work was oriented primarily to problems of population exposures.

The thrust of the work was continuous exposure of rats in utero. Pregnant rats were maintained at constant body activities of HTO by intraperitoneal injection (Cahill and Yuile, 1970, with a preliminary report at the 1969 Hanford biology symposium). There were 101 animals kept at levels from 1 to 100 $\mu\text{Ci}/\text{ml}$ of body water. The calculated associated doses to embryo and fetus were approximately 0.3 to 30.0 rad/day. It was found that T levels in the fetal organs were from 20% to 30% of the average maternal HTO body-water activity.

Progeny were grossly normal. All organs except gonads were normal histologically. However, microencephaly (small head size), sterility, stunting, litter size reduction, and increased resorption were significant findings. These were dose related, but did not occur except at the higher doses. Weight and length of both male and female progeny were statistically reduced at all levels above 20 $\mu\text{Ci}/\text{ml}$. At 1 $\mu\text{Ci}/\text{ml}$, only the length of the progeny was changed (statistically significant at $p < 0.05$ level) and this was an increase.

The authors concluded that a maternal level of 1 $\mu\text{Ci}/\text{ml}$ during pregnancy is consistent with normal progeny except for the possibility of slightly increased length.

Three years later, after Cahill had set up operations at the National Environmental Research Center in North Carolina, the work was extended to the succeeding generation. The levels of HTO were 0.01, 0.1, 1.0, and 10.0 $\mu\text{Ci}/\text{ml}$ of body water (Laskey, Parrish, and Cahill 1973). Administration was via drinking water. Doses were calculated at 0.003 to 3 rad/day. The F_1 litters were delivered naturally, weaned at 21 days, and a dozen males and females continued on the HTO regimen. At 110 days, the females were mated to males from different litters, and exposure continued to delivery of the F_2 generation.

There was a significant reduction (30%) in the weight of the F_1 male testes but no apparent impairment of growth or fertility. In the F_2 neonates, there were reductions in brain weight at the 0.1- and 10- $\mu\text{Ci}/\text{ml}$ level, decreased body weight at 1.0 and 10.0 $\mu\text{Ci}/\text{ml}$, decreased litter size, and increased resorption of embryos at the highest level. Highest levels of HTO content of tissues were reached during the in-utero phases of exposure. Comparison to similar work with x-irradiation indicated comparable but far from identical effects. An important conclusion was that the lifetime exposure regimen produced effects at much lower doses than those required to produce the same effect by in-utero exposure only. There is no way genetic and somatic components could be distinguished.

The minimal level of effectiveness, 0.1 $\mu\text{Ci}/\text{ml}$, corresponds to about 30 mrad/day and the intake to twenty times the maximum permissible concentration in water.

Later work done at North Carolina with collaboration from other laboratories explored the incidence of neoplasms and life-span effects in adults exposed during pregnancy to a greater range of tritium body water contents (1 to 100 $\mu\text{Ci}/\text{ml}$). There was an increased incidence of mammary fibroadenomas at the two highest levels (330 and 660 rad). Also, postexposure life spans were reduced by 14%, 24%, and 22% at 66, 330, and 660 rad, respectively (Cahill et al. 1975a). Rats exposed in utero from conception to birth showed more striking effects. The offspring were sterile after in-utero exposure to 330 and 660 rad (Cahill et al. 1975b). The sterile females had a lower incidence rate of mammary

fibroadenomas than controls, and the life span of both males and females was reduced. The protective effect of sterility did not appear to extend to tumors of the pituitary. Interestingly, the results of this work appear to be in reasonable agreement with effects of x-irradiation of mice at various postconception and postnatal ages. Three hundred rad seemed to be the lowest dose for consistent effects from either tritium or x rays.

In a more biochemical approach, the Research Triangle people, with help from L. N. Parker in the Division of Endocrinology at Harbor General Hospital, Torrance, California, delved into brain neurochemistry following intrauterine exposure to tritium as HTO. The levels and calculated radiation doses were as in the work just quoted. The primary changes were decreases in brain weight and increases in norepinephrine concentrations at doses as low as 66 rad. Exposure in utero to 6.6 rad produced no detectable changes in the biochemical parameters measured (Bursian et al. 1975).

By 1975, Cahill and his coworkers were delving into possible synergistic effects of tritium and a common environmental pollutant, lead. The same technique was used with HTO and/or lead through two generations of rats. The HTO activities were 0, 0.01, 0.10, or 1.0 $\mu\text{Ci}/\text{mL}$, while the lead concentrations were 0, 5, or 50 ppm. Radiation doses from the HTO were calculated to be 3 to 300 mrad/day (0.003 to 0.3 rad/day).

In this work (Cahill et al. 1976), many new parameters were added. Some pups were tested for the development of their startle pattern, the righting reflex, and eye-opening time. Locomotor activity was measured in others using a "residential maze" kept in a sound-proofed room. They also did electroencephalograms and catecholamine assays, in addition to the organ weight observations of earlier work. (This array of observations is refreshing after the single-minded concentration on cancer seen in so much of the work in radioisotope toxicology.)

The results were interesting but not indicative of serious effects. There was a transient body-weight deficit in the F_2 generation of the animals receiving HTO and some elevations of urinary excretion of moieties associated with marginal lead intoxication. Both HTO and lead delayed development of the central nervous system insofar as the administered tests could indicate. When the effects of HTO + Pb are compared to either alone, it appears that the combination was less than additive. Nevertheless, it was concluded that continuous exposures at levels as low as 3 mrad/day from HTO or 5 ppm of lead can yield "biologically important consequences in mammals."

The Brookhaven program was extensive. The four major areas studied are shown in figure 10.9.

Some of the work was very similar to that done by Cahill. An interesting twist was the use of deuterium as a stable isotope tracer for tritium in situations (e.g., primary oocytes) where it would be necessary to maintain the mother on undesirably high levels of tritium in order to get enough incorporation for counting or autoradiography. We will see various facets of the Brookhaven experiments in the balance of this chapter and in chapter 20.

Genetic effects of long-term tritiated water ingestion were studied by Carsten and Commerford (1976) at Brookhaven who looked at dominant lethal mutations in mice. The exposure level was 3 $\mu\text{Ci}/\text{mL}$, and the study was conducted on the second-generation females. There was a significant reduction of viable embryos but no effect on breeding efficiency. Since the system of the experiment was built around the detection of dominant lethal mutations, the authors

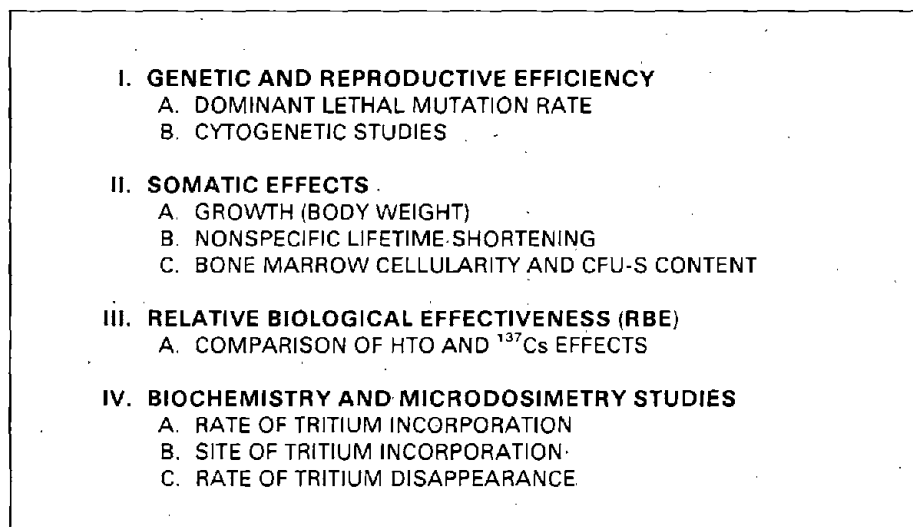

FIGURE 10.9. Brookhaven Tritium Toxicity Program. (Courtesy of Dr. Arland Carsten.)

attribute the changes to genetic rather than somatic processes. Radiation doses, based upon tritium incorporation values, were 0.36 and 0.48 rad/day to ovary and testes, respectively.

Hematological as well as genetic effects were reported by Carsten and Cronkite (1976) at the IAEA symposium on low-level radiation effects. Over 18,000 mouse embryos were examined. The HTO level was, as before, 3 $\mu\text{Ci}/\text{ml}$ placed in the drinking water. Not only was there a significant difference in number of viable embryos but more early deaths in the HTO group. The hematological work concentrated on bone marrow. While there was no change in total cellularity of the bone marrow (leg), the relative number of pluripotent stem cells^(a) was markedly depressed. This began about twelve weeks in the second generation and continued throughout the eighty-week observation period. The radiation doses were about 120 rad to bone marrow for the first twenty-five weeks, but only 31 rad for the second generation ovaries and embryos—and this was an overestimate because of very conservative assumptions.

An experiment on genetic effects of tritium was also conducted at the Biology Division, Oak Ridge National Laboratory. In one of the first experiments using the classic specific-locus mutation technique for an internally deposited radio-nuclide, Russell et al. (1979) gave single^(b) intraperitoneal injections of tritiated water to male mice at 0.75 or 0.5 mCi/g body weight. The estimated radiation dose to the germ cells was 430 and 615 rad to different cell stages of the spermatogonia. The treated mice were then mated to a stock that is homozygous for

(a) Cells with potential for production of many different types of mature cells.

(b) Since only a single injection was given, this experiment does not qualify formally as being in the chronic exposure category. Since the results occur over a generation, we choose to discuss it in connection with the other long-term effects of tritium.

seven recessive marker genes. The induced mutation rate for the offspring of males irradiated in the postspermatogonial stage was 44×10^{-8} per locus per rad, and 15×10^{-8} per locus per rad for irradiated spermatogonial stages. The distribution of mutations induced among the loci by tritium was quite comparable to that seen with x- or gamma-radiation. The mutation rates for the postspermatogonial stages were slightly lower than for external radiation, while those for the spermatogonial stages were higher by a factor of up to two. In view of the problems of the microdosimetry of tritium, the authors caution that the ratio of rates may not be significantly different from 1, but in view of the importance of the spermatogonial stage and of possible dose-rate effects, it might be prudent to adopt a ratio of 2 for radiation protection work (see section on RBE of tritium).

At Los Alamos, Storer et al. (1957) maintained relatively constant levels of tritiated water for five days in mice. The spleen and thymus were found to be atrophied, and the red cells took up less ^{59}Fe than normal cells.

All of this work on chronic exposure to tritium and its effects at the whole-animal level point to effects at fairly low radiation doses.^(a) The Brookhaven people promise work at still lower concentrations of HTO. Extrapolation to humans is difficult because of the differences in water turnover rate, but the information should be fed into any analysis of the environmental consequences of tritium releases.

It should be emphasized again that the route of administration for much of this work was not inhalation. However, as stated earlier, we have assumed that the great mobility of T in the forms we have been discussing makes the route of administration of little consequence. This obviously may not apply to every detail, and it certainly does not apply to luminous paint compounds containing tritium.

D. Toxicology of Tritium at the Cellular Level

The extremely low energy of the beta emission of tritium poses some special problems concerning effects at the cellular level. Since the mean range of tritium beta particles in water is only $0.69 \mu\text{m}$, and the maximum range is $6 \mu\text{m}$, a significant fraction of the deposited energy can be absorbed in single cells, even single cell nuclei. A reference cell nucleus is frequently taken as about $8 \mu\text{m}$ in diameter. The only other common isotope with so much energy deposition in a small volume is ^{125}I , which is special because of the involvement of Auger electrons.

To a degree, the concerns here are grossly comparable to those we saw in chapter 9 as the "hot particle problem." However, here we are at a more micro level. Concern was exacerbated by the growth of uses of tritium (and iodine) for labeling cell macromolecules, including the precursors of DNA. It became clear rather early that tritium-labeled thymidine inhibits the growth and survival of cells in tissue culture, and of ascites tumor cells; causes changes in cell ploidy; causes chromosome aberrations in plants, leukocytes, and regenerating rat liver cells; produces mutations in the germ cells of mice and in bacteria; and can

(a) Remember the doses given are cumulative doses occurring over a significant period.

induce cancer (Dewey, Humphrey, and Jones 1965). The work was done largely at the centers for tissue culture and cellular radiobiology, e.g., M.D. Anderson Hospital in Houston, Brookhaven National Laboratory, Lawrence Livermore Laboratory, Oak Ridge National Laboratory, University of Rochester, and Ohio State University. Gradually, nearly every radiobiology and nuclear medicine laboratory was either concerned with the problem or actively experimenting on some aspect of it because of the ubiquitous use of labeled nucleic acid precursors.^(a)

An additional concern was the possibility of a transmutation effect, i.e., a distortion of the chemical bonding, and thus molecular configuration, of biologically important molecules by the transmutation of hydrogen—a very reactive element—to helium—a very unreactive element. It took very careful study in many laboratories, especially Brookhaven and some laboratories abroad, to put this concern to rest. Since the problems and experimental investigations are much more pertinent to the uses of tritium in nuclear medicine than to inhalation problems, we will reserve the full story for chapter 20.

Suffice it to say here that the preponderance of evidence is that all effects can be accounted for by the radiation dose. Transmutation effects are negligible, except in the possible case of one particular labeled nucleic acid precursor.

E. The Relative Biological Effectiveness of HT and HTO

We enter here an area that has commanded large investments of time and energy in radiobiology. We have had little to do with it so far in this book, and, therefore, a short background statement is in order. The RBE problem concerns the fact that the same absorbed dose of ionizing radiation has different degrees of effectiveness, depending upon the "quality" of the radiation. The most common differences in "quality" are between photon radiation, such as x or gamma rays and beta particles on the one hand and neutrons, alpha particles, fission fragments, and the like on the other. A ratio called the relative biological effectiveness can theoretically be derived for any comparison of effectiveness of different radiations. The RBE is defined as:

$$\text{RBE} = \frac{\text{Dose of reference radiation}}{\text{Dose of experimental radiation}}$$

where the doses measured are those required to produce *the same degree of the same biological effect in a given organism*.

Thousands of determinations of this ratio have been made for organisms ranging from bacteria and viruses to the primates using a large number of biological endpoints. A tradition has grown to use low linear-energy-transfer (LET) radiation, such as radium gammas or 250-kv x rays, as the reference radiation. The fact that internally deposited radioisotopes differ from each other in ways other than radiation quality, e.g., site of deposition, half-life, movement within the body, etc., means that determination of a "pure" RBE as defined above is usually not possible. The toxicity ratios we discussed in chapters 7 and 8 have sometimes been termed relative biological effectiveness factors, and there is no

(a) We have arbitrarily considered genetic changes caused by HTO in the section on whole organism studies because it is in the whole organism that we see the results of the mutations. Obviously, the process itself is a cellular-level phenomenon.

reason the term cannot be applied except for the tradition that has grown up around the definition as given. Because of the possibility of determining relative effectiveness of two types of radiation uncomplicated by half-lives, distribution of isotope, etc., the bulk of the experimentation with RBE has been done using external radiation sources rather than internal emitters.

The now classic report of R. E. Zirkle at Chicago, published in the Met Lab report series (Zirkle 1943), established that the differences in effectiveness of the same dose to different radiations could be correlated with their ion density or "specific ionization." Subsequently the term "specific ionization" was replaced by the term "linear energy transfer" and the relative effectiveness predicted from the LET. Further discussion would carry us too far into basic radiobiology for the purposes of this book. The interested reader can find ample discussions of the subject in any of the numerous texts or monographs in radiation biology.

As we will see in chapter 16, account is taken of the differences between radiation qualities in calculating effective doses by introduction of a factor called the quality factor or "Q."^(a) Its value was derived largely from work with external sources, including another classic piece of work by Zirkle using the alpha particles from ^{210}Po .

Much interest in the possible RBE and derivable Q factor for tritium beta radiation arose because its very-low-energy beta particle had relatively high values of LET compared to most beta emitters. These might conceivably produce greater effects per unit of absorbed dose than the higher-energy beta emitters, as we hinted at earlier.

A first indication of results came from Argonne National Laboratory, where Brues and his colleagues followed up on the acute toxicity work already reviewed. Jennings and Brues (1951) compared toxicity of HTO in rats to known values for x-irradiation and found an RBE close to 1.

A second indication came from Hanford, where Getzendaner, Fujihara, and Kornberg (1953) reported an RBE of 2 for inhibition of growth of the bacterium *Lactobacillus casei*.

However, it was at Los Alamos that the first concentrated work was done. The laboratory already had a broad program on RBE, and there was also considerable interest in tritium for the reasons we saw earlier.

The early work done by Furchner and Storer in 1953 and cited by Storer et al. (1957) indicated an RBE of 1.4 to 1.6 for depression of the uptake of ^{59}Fe by rat red blood cells. The comparison was between tritium and gamma rays from radium or ^{60}Co .

Spalding, Langham, and Anderson (1956) determined the RBE of tritium in affecting growth of the root of the broad bean (*Vicia faba*). (This was the system used with great effectiveness over almost two decades by L. H. Gray in England.) They grew the bean roots in culture cells that allowed immersion of the root system in HTO or exposure to x-irradiation from a 250-kvp Maxitron machine. The actual energy to the bean roots was about 175 kvp.^(b) A graph of the response as a function of dose showed the points for tritium irradiation and x-radiation essentially superimposable. In other words, the derived RBE was 1 (given as 1.0 ± 0.06).

(a) This is derived from the RBE by a judgmental process and is strictly for use in radiation protection. Conversely, the term RBE is now strictly for use in radiobiology.

(b) Several exposure arrangements were tried, but the results were not materially affected.

Worman, Turney, and Lotz (1954), also at Los Alamos, used thymic atrophy in the mouse and compared HTO to ^{226}Ra gamma-rays delivered at a constant rate for five days. The RBE value was about 1.5.

The ingenious experiment by Furchner (1957) at Los Alamos already described and referenced in chapter 8 compared tritium to ^{60}Co gamma rays, which were given with an exponentially declining dose rate to imitate the decay and excretion kinetics of HTO. The criterion was lethality using CF1 mice. In this system, the RBE appeared to be about 1.7.

The provisions for an external dose rate that imitated kinetically the exponential decrease of the radioisotope lent special credence to the RBE value for this experiment.^(a)

In their monumental analysis of RBE studies in mammalian systems, Storer et al. (1957) at Los Alamos quote work involving splenic atrophy, thymic atrophy, and depression of ^{59}Fe uptake. The RBE values were 1.3, 1.5, and 1.6, respectively. Graphs showing the relationships of splenic weight loss, thymic weight loss, and uptake of ^{59}Fe to radiation dose are shown in figure 10.10A, B, and C, taken from the Los Alamos work.

Note the almost identical slopes of the trend lines over a considerable range of dose, and thus constancy of the ratio, i.e., RBE, with dose. This is far from universally true. It is more likely with radiations of low and roughly comparable LET, but, as we shall see, such constancy does not apply to even all of the tritium work. The Los Alamos workers were very skilled, but we have to admit to there being a certain element of luck in the beauty of these first experimental results.

FIGURE 10.10A. Splenic weight loss in mice at 5 days as a function of dose of tritium beta-particles and radium gamma-rays. (Redrawn from Storer et al. 1957. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1957.)

(a) The only other experiment extant with a similar exponential decrease of external radiation dose for the reference radiation is one by Lambert in the United Kingdom (1969). He used the ability of intermediate spermatogonia to divide twice as the criterion of effect. The RBE against HTO was from 2.0 to 2.4.

FIGURE 10.10B. Thymic weight loss in mice at 5 days as a function of dose of tritium beta-particles and radium gamma-rays. (Redrawn from Storer et al. 1957. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1957.)

FIGURE 10.10C. Uptake of Fe^{59} by rat red blood cells as a function of dose of tritium beta-particles and radium gamma-rays. (Redrawn from Storer et al. 1957. Reprinted with permission of Academic Press, Orlando, Florida, copyright 1957.)

Thus, the early work suggested that tritium beta particles may be slightly more effective than classic low-LET radiations. For radiation protection purposes, a quality factor (chapter 16).

The idea that the value for the RBE for tritium is greater than 1 was strengthened by the results of Lambert, for example, who indicated that the nucleic acid precursor, tritiated thymidine, might be more effective than HT or HTO.

A summary of the RBE data including their ranges of uncertainty is shown as figure 10.11.

Much more work was done, subsequently at the cellular level at a variety of institutions. These showed a greater range of values than the work quoted, including many that approached 1. Examples of the latter are the production of chromosomal aberrations in Chinese hamster cells exposed in vitro to HTO and ^{60}Co gamma rays by Dewey, Humphrey, and Jones (1965) working at Houston (RBE values 1.2 or 1.06), and clonal growth of HeLa cells at a dose rate of 32 rad per hour by Hall, Oliver, and Bedford (1967).

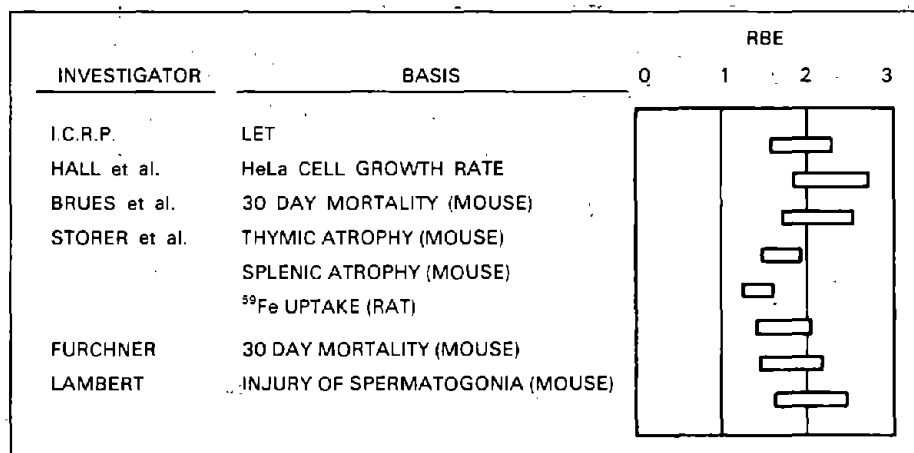

FIGURE 10.11. The ranges of uncertainty in RBE for tritium; data of various investigators. (Redrawn from Johnson 1973. Reprinted with permission of Messenger Graphics, Las Vegas, Nevada, copyright 1973.)

Indications that the RBE was subject to variation depending on conditions appeared in both the work with HeLa cells and the work with bean roots done by Hall and colleagues. Changes in dose rate of the reference radiation could produce variations by a factor of two. Further indication of variability under different conditions was seen in work at Berkeley by Dobson (1976), who studied the survival of oocytes from mice that had been treated for shorter (e.g., five days) or longer (e.g., thirty-three days) periods with HTO or ^{60}Co gamma rays. An example of the results taken from Dobson and Kwan's 1976 work is shown as figure 10.12.(a)

FIGURE 10.12. Oocyte responses to ^3HOH and ^{60}Co gamma-rays given in short (5-day) and protracted (33-day) exposures compared. (Redrawn from Dobson and Kwan 1976. Reprinted with permission of Academic Press, Inc., Orlando, Florida, copyright 1976.)

(a) The marked variability of RBE values with choice of biological endpoint is not by any means limited to tritium. Both it and effects of dose rate and of total dose are ubiquitous. Indeed, they have to be when the underlying radiobiology is appreciated.

Even before the work of the 1970s, those responsible for recommendations in radiation protection had begun to have second thoughts about the use of a quality factor of 1.7 for low-energy beta particles. Two definitive reviews and critiques appeared in the late 1960s and early 1970s; one by Vennart (1968) at the Radiological Protection Service in the United Kingdom, the other by Johnson (1973) domiciled at the State University of New York at Stony Brook, but obviously in close touch with the Brookhaven group. Both conclude that the RBE values have so much range and include so many uncertainties that no value except 1 can be supported for radiation protection work. This applies even to the nucleic acid precursors and includes transmutation effects (Feinendegen and Bond 1973).

Thus, in a sense, the field reversed itself in its interpretation of the findings.^(a) By the time of the NCRP report on basic radiation protection criteria (NCRP 1971) we find the following footnote to the table giving practical quality factors:

In 1966 the ICRP^(b) recommended a value of 1.7 for the QF of low energy electrons or protons. We believe that a rounded value of 1 is more commensurate with the accuracy of our knowledge and the requirements of radiation protection. (In 1969 the ICRP amended its 1966 recommendations, specifying that the QF should be taken as 1 for all β^- , β^+ , e^- , γ and x radiations, and for conversion electrons). (NCRP 1971, table 5)

Work from Oak Ridge published in 1976 compared tritium and plutonium in producing chromosome aberrations in *Chironomus riparius* (Blaylock and Trabalka 1976) with the surprising finding of a relatively lower effectiveness of plutonium in this system than is usually expected from its RBE of 10 to 20 or more. However, in general, the work with tritium in no way puts it in the class with plutonium as a toxic agent.

Carsten and Cronkite, at Brookhaven, compared late effects of single x-ray exposure, chronic ^{137}Cs gamma exposure, and chronic tritiated water ingestion in mice. The work is fairly recent, reported at the 1979 IAEA Symposium on *Biological Implications of Radionuclides Released from Nuclear Industries* (Carsten and Cronkite 1979). The criteria were primarily hematological. It was not possible to determine whether there is a significant difference in effectiveness of the two chronic modalities. The authors conclude "indications are that they are similar."

Some work has continued on the RBE for tritium beta particles. There are grumblings from the "pure" scientists that the preponderance of evidence indicates that tritium beta particles are more effective than very low-LET radiations, just as there is growing evidence that 250-keV x rays, with a higher LET than radium gammas, are slightly more effective (by perhaps a factor of 1.3). There are indeed ample theoretical reasons that particles in the LET range of the beta particles of tritium, especially if the tracks happen to bend back upon themselves, should deliver a higher local dose than radiations with minimal LET. However, those making recommendations for radiation protection are equally disposed to grumble about the validity of the RBE data and to doubt that there is evidence enough to support any Q value but 1.

(a) Note that this applies only to the practical use made of the RBE values and in no way reflects on the interest in and importance of the findings toward understanding radiobiological mechanisms.

(b) ICRP 1966.

Despite these differences, which are more in point of view than anything else, the work on the RBE for tritium can be viewed as of real interest and significance. It brought many of the radiobiologists who had never worked much with radioactive isotopes—at least vis-à-vis internal emitter toxicology—into the field. It brought to light some quite basic and important scientific questions, only some of which centered around HT and HTO.

F. Work with Tritium Abroad

Throughout this book, the need to concentrate on U.S. work has frequently caused us to give short shrift to meritorious work in other countries. Since the bulk of the work with tritium was done in the postwar years, and it has attained great popularity in tracer chemistry, a large effort was expended everywhere on questions of its toxicity. Thus, we are having to by-pass an especially large amount of good work abroad on this subject.

We did glimpse briefly the work with the Swiss luminizers and some of the U.K. work that tied most closely to subjects we were discussing. A review of the several symposia and monographs cited in section IV A will give a reasonable picture of what went on in other countries. In addition, special mention should be made of work that the Commission of the European Communities sponsored, viz., a full review of tritium much like the one prepared for the AEC by Jacobs (1968) but more biomedical in emphasis. This was prepared for the Comitato Nazionale per l'Energia Nucleare (CNEN) by Silini, Metalli, and Vulpis (1973). Also, special mention should be made of the enormous effort in the Soviet Union, represented by a book edited by Moskalev (1968) and several papers on tritium in the 1966 compendium also edited by Moskalev (1966, section III).

The CNEN document addresses both metabolism and toxicity of tritium in mammals and applies the information to dosimetry. They make even more of the "special problems" associated with tritium dosimetry than we have. They take up the physical problems of the short track length and "microscopic physical heterogeneity" along the lines we have already discussed. In addition, they introduce the concept of "microscopic biological heterogeneity." This is based on possible differences in tritium concentrations in particular cellular or subcellular components and the consequent variations in the structure irradiated. They emphasize evidence from microautoradiography (which we have had to treat very lightly) that shows possible inhomogeneous disposition of tritium within nuclei and chromosomes at the metaphase stage of cell division and muse on the fact that such differences do not seem to account for the differences in dose estimates. The majority of experimental work quoted in this document is U.S. work. It appears that the CNEN laboratories did not themselves engage deeply in biological research with tritium.

The work from the Soviet Union, on the other hand, covers the entire field with detailed experimental studies. The research that deals with the same problems as we have described for the U.S. work comes to approximately the same conclusions. Their RBE experiments tend toward ratios between 2 or 3 rather than between 1 and 2. They show no disposition to use a lower figure for radiation protection. In the chapter on maximum permissible concentration of tritium, they use an "RBE coefficient" of 3 (Moskalev 1968, p. 353).

The USSR work goes into much more detail on histopathology, even though the picture closely resembles the radiation syndrome from external sources.

Also, they add effects on immunological reactivity, effects on enzymes, and studies on embryos, fetuses, and newborn, with results fairly similar to the U.S. work.

The work abroad and that in the United States agree in general, but some interpretations differ.

V. Radioactive Carbon Dioxide

A. Overview

"Atmospheric carbon dioxide is the major source of the carbon in all living organisms" (NCRP 1985). Despite this truism, atmospheric radioactive carbon dioxide (with ^{14}C) is of almost no practical importance in pulmonary radiotoxicology. The reasons for this apparent contradiction are manifold. Some of them are:

1. A large portion of the carbon in the atmosphere gets incorporated into plants by photosynthesis. The radiocarbon is distributed among the many products of photosynthesis.
2. The major intake of radiocarbon by man is by ingestion, either of plant material or of animal products that have incorporated the carbon from ingestion of plant materials.
3. By far the largest reservoir of carbon is the oceans. Transfer to man involves many steps, of which inhalation is quantitatively a very minor one.
4. Inhaled radioactive carbon dioxide is diluted in the lungs by the carbon dioxide always present in the lungs. Its specific activity is materially reduced thereby.
5. The long half-life (5,730 yr) and low energy (0.156-MeV maximum beta energy) of ^{14}C mean that few of the inhaled radioactive atoms decay in the lung or even in the body if absorbed, and those that do decay contribute only small radiation doses.

Despite knowledge that radiocarbon was produced by neutron activation processes in fission reactors and fission weapons, the facts enumerated above must have convinced the biomedical teams of the Manhattan Project that they had more urgent problems to consider than the possible inhalation of radioactive carbon dioxide. Thus, although the tracer uses of ^{14}C continued and grew during the war, there was very little toxicology done. Even in the post-World-War-II years, when it was evident that much more radiocarbon could be produced in the fusion process, biomedical work remained sparse insofar as radiotoxicology was concerned.

There are a few calculations and one or two experiments that should be described because of their direct bearing on potential inhalation problems. We will examine these here with the understanding that the enormous efforts that went into environmental aspects of the ^{14}C problem belong in later chapters.

B. Sources of Radioactive Carbon Dioxide

As we saw in chapter 5, long-lived radiocarbon (i.e., ^{14}C) was prepared by Kamen and Ruben in 1940 by bombarding graphite enriched with ^{13}C with low-energy deuterons. Because of the key role of carbon in biochemistry, the new radioisotope became instantly popular for applications in tracer chemistry.

(chapter 5). Libby (1955) first identified the presence of ^{14}C in nature. It is now well known that it is produced at a roughly constant rate, except for changes in ambient flux, by reactions of cosmic ray neutrons with a number of elements, the most important being nitrogen, oxygen, and carbon, in that order. As the atomic energy project developed, it was obvious that ^{14}C was produced at many points in fission reactors and in both fission and fusion weapons. The world inventory of radiocarbon was increased considerably by the atmospheric testing. Whereas the average production of ^{14}C by interaction of cosmic rays with elements in the upper atmosphere is about 0.038 MCi/yr, and the global inventory is about 3.8 MCi in the atmosphere,^(a) about 9.6 MCi of ^{14}C have been introduced into the atmosphere by thermonuclear explosions alone.^(b) The maximum level, at about 1963, was 350×10^4 Ci in the stratosphere and about 275×10^4 Ci in the troposphere.

All nuclear reactors produce ^{14}C . Like our estimates for tritium, the projected amounts are subject to considerable uncertainty because of imponderables regarding the future development of nuclear energy. The NCRP report (1985) declares that the bulk of the releases from reactors are to the atmosphere rather than to liquid effluents. The same is true of fuel processing. The amount expected to be released through 1990 is 235 kCi with 12.1 kCi released by the nuclear industry through 1970. The graphite-moderated and heavy water reactors account for more than the light water cooled reactor or the fast reactor. It can be seen that this amount is much smaller than that released by atmospheric testing of weapons.

A final source of radiocarbon is in the labeled compounds used in medical and biological research. The U.S. Department of Energy estimates the amount as between 100 and 500 Ci annually.^(c) This carbon is unlikely to be available for inhalation unless incinerated. However, we must remember that the metabolism of carbon compounds by most organisms of interest to us results largely in carbon dioxide and urea, which are returned to the environment and reenter the cycle.

Obviously, in many respects the source-term aspects of radiocarbon resemble those we reviewed for tritium. However, it is even more an environmental distribution problem and even less a direct inhalation problem than is tritium.^(d)

C. Uptake and Retention

In essence, the behavior of ^{14}C follows stable carbon, although there is a small isotope effect in the synthesis of some compounds. The processes of uptake and retention of ^{14}C are, of course, regular grist for the mill of biochemistry. But the source is characteristically food or parenteral administration. Thousands of experiments bear on this aspect. By contrast, very few experiments have been aimed at uptake and retention of inhaled radiocarbon. Principal among these is work from Argonne National Laboratory.

(a) Do not forget the ultimate sinks are the oceans and rocks.

(b) The yield is primarily from fusion weapons.

(c) Actual amounts are proprietary information of the pharmaceutical industry.

(d) If this is the case, why have we bothered to review the subject? The primary reason is that we need to know why inhalation is considered unimportant, and the story provides important background for our environmental discussions to come.

The work was initially aimed at hazard evaluation, but this aspect gradually became secondary to the development of knowledge of the metabolism of inhaled carbon. Brues and Buchanan (1948) developed a "flushed chamber" apparatus, which exposed mice to atmospheres of $^{14}\text{CO}_2$ in nitrogen/oxygen introduced from cylinders. This was a static atmosphere, which was renewed by periodic flushing.

It was soon apparent that absorption of $^{14}\text{CO}_2$ from the lung was very efficient in spite of the mass movement of metabolically produced CO_2 in the other direction. Equilibrium values in the blood bicarbonate reflected faithfully the specific activity of the alveolar CO_2 . Since alveolar pCO_2 is not changed much by reasonable changes in inhaled CO_2 concentration, this meant reasonably constant blood ^{14}C bicarbonate. Only if the inhaled pCO_2 was high enough to cause hyperventilation was the rate of absorption accelerated.

Removal rates on cessation of exposure were essentially a mirror image of the uptake, except for a small fraction with a longer retention time.

Autoradiographic work with chick embryos showed rather long retention of the incorporated ^{14}C , since it had been built into growing tissues including bone.

This immediate postwar work was expanded on by Buchanan (1951). He used a more complex exposure system, which held the pCO_2 and the specific activity constant. Again, the original purpose was radiotoxicity. Finding none, they used the system as an excellent way to introduce labeled carbon in a steady state situation. The exposure levels ranged from 0.03% to 5% CO_2 in air. Exposure lasted as long as forty days, and retention was measured out to fifty days after termination of exposure. He determined the specific activities of many tissues and compared them to the specific activity of the inhaled air. The value of this ratio ranged from zero at the outset to about 10^{-4} after forty days. The equilibrium level of specific activity never exceeded 10^{-4} , or about 0.01% of the specific activity of the air breathed by the mice, an unexpected result. There were significant differences among the tissues.

These results led S. R. Bernard (1973) at Oak Ridge^(a) to a careful analysis and development of new metabolic models for ^{14}C . He showed that the average mouse inhales only 0.005 g of carbon per day, whereas it eats 4 g of food a day, one-fifth of which is carbon. This yields 0.8 g of carbon per day from food or a factor of $0.005 \text{ g}/0.8 \text{ g}$ or roughly 10^{-2} . This accounts for one-half of the 10^{-4} factor found by Buchanan. A second factor of 100 is deduced by considering that alveolar air normally contains 3% to 5% CO_2 or about one hundred times the concentration inhaled (0.03%). These two together round out the factor of 10^{-4} found by Buchanan. (Bernard goes on to apply the model to calculations of maximum permissible concentrations [now "derived air concentrations"] and suggests that figures derived from the old models may be substantially in error.)

Buchanan and Nakao (1952) made sure that equilibrium conditions prevailed by having rats and mice continuously inhale labeled CO_2 . Relative specific activities of soft tissue and bone reached about 70% of the specific activity of alveolar CO_2 , while arterial blood reached full equilibrium. The specific activity

(a) Of the major U.S. laboratories, Oak Ridge and Argonne have shown more activity in this particular aspect of radiocarbon behavior than any other. Those concerned at Oak Ridge were either interested in dose estimation and standard setting (e.g., Bernard, Snyder) or in environmental aspects (e.g., Rohwer, Killough).

of alveolar CO_2 was always much lower than ambient, in agreement with Buchanan (1951). Soft tissue labels were lost quickly, but some fractions of the bone carbonate retained the label for significant periods. This was a function of age and duration of exposure. Approximately 30% of the bone bicarbonate was replaced in twelve days, but only 45% was replaced in three months. These longer retention times of significant fractions raised some questions about the innocuousness of ^{14}C . However, the then-extant maximum permissible concentration of $^{14}\text{CO}_2$ for continuous exposure (about $10^{-6} \mu\text{Ci}/\text{m}^3$ of air) probably was sufficiently conservative to allow for this. Buchanan and Nakao calculated a much higher allowable concentration.

The fraction of radiocarbon retained after injection of $\text{NaH } ^{14}\text{CO}_3$ into mice was well described by a power function of time (Skipper as quoted by Bernard 1973). The function was $1.4t^{-1/2}$, a relatively slow loss rate compared to the noble gases and the bulk of inhaled tritium. However, it appears that only 1% of inhaled ^{14}C is taken into the blood (i.e., remains there for any significant period) in the mouse. If this holds for larger animals and man, it would require very large exposures to reach significant doses. There are apparently no experiments, except tracer experiments for other purposes, in larger animals or man to check out these low incorporation figures. If they were to be considerably higher in other species, the fairly long retention time (for a "gas") could lead to some more consequential doses. It is surprising that more work has not been done in this area.

It is clear from a large amount of biochemical and tracer work that respiratory CO_2 can enter into all organic components of the body and tissues except for a few substances that are not synthesized by the body. However, the compartments in which the compounds are produced are, except for some parts of bone, subject to rapid turnover. Thus, the labeled carbon is readily lost to either expired air or excretion as urea. One or two days suffice to wash out almost all of the radiocarbon taken in (Hellman et al. 1953, Baker et al. 1954 as quoted by NCRP 1985). The exception is mineral bone, which may have specific activities after inhalation of radioactive carbon dioxide twenty-six-fold higher than the organic carbon (NCRP 1985).^(a)

D. Effects

Essentially no direct experimental work has been done with inhaled radioactive carbon dioxide at levels that would produce radiation effects. Such would be impossible because of the marked effects of CO_2 on respiration. We are again relegated to the computational approach. Calculation of doses based on equilibrium with present global environmental levels of ^{14}C predict doses of about 1.5 mrem per year to the individual member of the population. Only a small fraction of this would be from inhalation. Even with very significant localized events, very large factors and very special conditions would have to enter to make the inhalation dose take precedence over others.

Additionally, there is little likelihood that the mean dose will increase with time unless very large additions to global radioactivity occur. This is because of the constant addition of stable carbon (^{12}C) from the burning of fossil fuels in one or another form. This keeps the specific activity down and essentially unchanged.

(a) But there is more organic carbon than inorganic carbon, even in bone.

The calculated maximum permissible air concentration for ^{14}C as $^{14}\text{CO}_2$ is $4 \times 10^{-6} \mu\text{Ci}/\text{cm}^3$ (with fat as critical organ), while that for tritium is $5 \times 10^{-6} \mu\text{Ci}/\text{cm}^3$ with body tissue as critical organ (ICRP 1959)—very similar.

The same concerns occur regarding genetic change with ^{14}C in an incorporated radionuclide as we saw with tritium. Much less has been done than with tritium. Hence, we will have to content ourselves with the almost certain knowledge that inhalation would contribute little in any event. If our mutual patience holds, we will look briefly at ^{14}C incorporated in genetic material in the chapter on nuclear medicine.^(a)

VI. Summary and Commentary

Some of the earliest inhalation problems anticipated in the days of the Manhattan Engineer District concerned the radioactive noble gases expected to be produced in the fission process. Because these gases move much more freely than particles and are less likely to combine with cell or tissue constituents, there is little tendency for long retention of these substances. Yet, there were a few substantive biomedical problems that required investigation. Most important concerned iodine vapor (plus the compounds formed after the vapor condenses); tritium in its various forms; and to a lesser degree, krypton, xenon, and radioactive carbon dioxide.

Unlike the concentrated attacks on inhaled dusts and particles through organized centers, the work on the respirable gases was more diffuse and on a smaller scale. Experimental work on iodine was concentrated to some extent at Hanford, tritium received major attention at Argonne, Brookhaven, Los Alamos, Savannah River, and the EPA laboratories. The noble gases were looked at especially by laboratories of the U.S. Public Health Service and their EPA-operated successors.

Iodine, as an important constituent of reactor off-gases and of fallout from nuclear weapons tests, is the element in this group that poses the most practical problems (see chapters 11 and 12). With most of the others (even tritium, which can be produced in large quantities) the experimental work has had as much or more scientific interest as practical import. With tritium and ^{14}C , the potential for transmutation effects at the time of radioactive disintegration of a nucleus was especially intriguing. Much research went toward divining whether or not the decay of one of these atoms within the intimate structure of the cell nucleus could produce effects over and above those associated with the radiation dose. The answer was positive for tritium, but only under special circumstances, viz., when the tritium was bound at certain specific positions in nucleic acid precursors. Since such specific binding sites are only occasionally labeled from a tritium pool, the effect is of little significance apropos tritium hazards.

Another intriguing aspect with tritium was its very low energy. Thus, all of the energy is deposited in a small volume. Would this increase the effectiveness per rad? For a while it seemed that it did, and a quality factor of about 1.7 for radiation protection was recommended for low-energy electrons and protons. This would include the tritium beta particle. However, subsequent research

(a) It is tempting in a situation with so many large gaps to inquire peevishly why no one has looked into them. (Perhaps someone has, but not in U.S. work.) It is likely that even if anyone were interested, he would have had trouble getting financial support for work that had such a high risk of being negative and "exactly as predicted."

indicated that this was not a sufficiently constant phenomenon to warrant use in radiation protection. An important practical factor in tritium exposure, however, is its absorption through the unbroken skin, a phenomenon that led to halving the allowable concentrations in ambient media.

Of special interest to basic radiobiology was the multigenerational study of neoplastic and life-span effects of tritium in rats exposed in utero and/or throughout life. On the basis of this work, we cannot dismiss tritium as a totally innocuous agent, even though it is not in the same class as strontium, plutonium, or even iodine.

Radiokrypton and radioxenon were rather exhaustively studied kinetically. The results belied the simple postulate that these gases moved freely about in living organisms. There was evidence of several components in the retention curves and thus of several compartments for their residence. Partition among organs was not uniform, due in part to different fat contents of different tissues.

The work with inhaled ^{14}C was initiated for hazard evaluation. Before long it became of more interest for the knowledge imparted on the pathways followed by inhaled carbon.

Preface to Section IV Environment Chapters

No book purporting to review the history of radioactivity and health would be complete without a discussion of the environmental aspects of the subject. Yet, consideration of these to the extent attempted for the more strictly laboratory research work taken up in other sections is impossible without greatly exceeding all reasonable restraints on the length of this work. While they were slow to start, environmental considerations now occupy enormous segments of the literature, and they continue to grow. Thus, the chapters in this section will constitute a change of pace from those that have preceded and those to follow. We will concentrate on the genesis of the major lines of investigation, give details where necessary and desirable; but make no attempt to provide documentation of the original literature to the extent attempted in many other sections. Fortunately, the field is so very active that current and excellent book-length reviews are readily available to the interested reader. Hence, much of the referencing will be to these, except for the earlier days.

Some facets of environmental exposures to radioactivity have already been discussed, including radium and radon in mines, spas, and drinking water (chapters 1 and 3); noble gases and volatile radionuclides as part of the review of respirable gases and particles (chapters 9 and 10). Others will appear in connection with the setting of standards (chapter 16). However, the research and problems considered therein were geared primarily to occupational exposure problems, although a few involved population exposures to a minor degree. By contrast, the focus and *raison d'être* for most of the work to be described in the chapters of this section are potential exposure of population groups, ranging from those around nuclear energy plant operations to all of mankind in the consideration of global fallout.

The work began with investigations oriented toward both worker and population exposures around nuclear production sites (chapter 11). It reached its full flowering in the events and research associated with fallout from nuclear weapons tests. Indeed, this new dimension changed the world as we knew it and continues to expand far beyond purely technical and scientific matters. Chapter 12 will review primarily the biomedical problems and findings coming from field studies on fallout, while chapter 13 will take up laboratory research stimulated by the problems identified in the field work. This research is closely related to some already reviewed, particularly in chapters 8, 9, and 10, but we

choose to discuss it in this section because of its extreme pertinence to environmental considerations and exposures of not only the human population but of all the biosphere.

Several projects were developed to study specific problems relating to potential environmental contamination on a more limited scale than the fallout from weapons tests. Many of these were designated "safety shots." Other projects involved purposeful dispersion of radionuclides in manners unrelated to weapons tests. They form a somewhat miscellaneous group that does not fit into other chapters. Yet, the results had important bearings on many environmental considerations. For these reasons, and perhaps because this author was personally involved with one of the projects, the work is drawn together separately as chapter 14.

The environment section closes with a brief review of how the research and field studies bear on our knowledge of environmental transport systems (chapter 15). This has become a highly sophisticated and complex field, which influences all of ecology, not just the phenomena concerned with radionuclides. Indeed, in many instances the radionuclides are more tools than ends in themselves. We can afford only a brief glimpse of this enormous field. Emphasis will be placed on the earlier work. The reader will be led to the more recent, more complex aspects, largely by references to current reviews.

It may occur to many that much of ecological science, as we know it today, developed from the research and field studies described or referenced in the chapters of this section. It would be presumptuous to conclude that it could not have happened through other avenues. Ecology is a very broad field. Only some aspects were materially changed by the work to be described. Nevertheless, there can be no doubt that some areas were very materially advanced and much sooner than they would otherwise have been. Nor can there be any doubt that ecology as a field was transformed from a quiet, somewhat academic subject into the limelight of both scientific and public concerns. The investigations reviewed in the chapters in this section should supply ample documentation for these conclusions.

In these chapters, we will have much to say about the field of radioecology. For orientation, the following quotations from a recent book by Whicker and Schultz (1982, see chapter 11) is presented:

"Radioecology" or "radiation ecology" can be considered a field of endeavor which encompasses the relationships between ionizing radiation or radioactive substances and the environment, or subunits within the environment. These subunits may be populations, communities, ecosystems, biomes, or even the biosphere. Radiobiology, in contrast, deals with radiation and levels of biological organization from the molecule to the organism. The primary subdivisions of radiation ecology include:

1. Radionuclide movement within ecological systems and accumulation within specific ecosystem components such as soil, air, water, and biota
2. Ionizing radiation effects on individual species, populations, communities, and ecosystems
3. Use of radionuclides and ionizing radiation in studies of structure and function of ecosystems and their component subsystems.

Questions commonly asked regarding movement, accumulation, and effects of radionuclides in ecological systems include:

1. How rapidly do radionuclides move from one part of the system to another and what are the mechanisms and pathways of such transfers?

2. What are the relative concentrations and radiation doses from radionuclides in important biological components relative to the total amount of environmental contamination?
3. What is the long-term behavior and ecological effect of radionuclides in the environment?
4. At what environmental concentrations are effects, if any, seen in populations?
5. Environmental studies using radioisotopic tracers may answer such questions as: Where do animals move? What do they eat? How much and which elements and nutrients are used? What are the dynamics of upper-lower atmospheric mixing? What are the circulation patterns of lakes and oceans?

Behavior of radionuclides in the environment is governed by a highly complex set of natural processes and circumstances. Nearly every component of an ecological system will have some influence upon the fate of radioactive materials introduced into the system. Of major significance, however, is the fact that natural processes may concentrate radionuclides in biological tissues to levels that are orders of magnitude higher than in the ambient media of air and water. Further, there is no doubt that radionuclides, in sufficient concentrations, are harmful to all living systems.

The authors believe that radioecology is an important, complex, and diverse science, dictating an interdisciplinary approach, which is accomplished in practice by the varied and unique academic training of radioecologists. The field draws heavily on information from the basic physical and biological sciences, and current curricula of the radioecologist may encompass physics, chemistry, mathematics, geology, plant and animal ecology and physiology, taxonomy, radiation biology, dosimetry, and more. Because radioecology integrates these fields, to some extent, it frequently leads to interdisciplinary contributions which can aid the extension of each discipline.

The work reviewed in these chapters has extensive ramifications for all problems of environmental contamination. As we stated in the inhalation toxicology section, it was the work directed toward radionuclides and radiation biology that led the way to a considerable extent.

The first of these is the fact that the
theoretical model of the system is
based on the assumption that the
system is in a steady state. This
assumption is not valid for the
system under consideration, as the
system is in a transient state.

The second of these is the fact that
the theoretical model of the system
is based on the assumption that the
system is in a steady state. This
assumption is not valid for the
system under consideration, as the
system is in a transient state.

The third of these is the fact that
the theoretical model of the system
is based on the assumption that the
system is in a steady state. This
assumption is not valid for the
system under consideration, as the
system is in a transient state.

The fourth of these is the fact that
the theoretical model of the system
is based on the assumption that the
system is in a steady state. This
assumption is not valid for the
system under consideration, as the
system is in a transient state.

Capsule Chronology

- April 1943** Ground broken for Hanford reactors.
- May 1943** Stafford Warren initiates activities for radiobiological studies of fisheries and ecological investigations of Columbia River.
- August 1943** First contract let between University of Washington (Applied Fisheries Laboratory) and OSRD^(a) (Donaldson et al.).
- 1943** Clinton reactor goes into operation at Oak Ridge, soon followed by other facilities of MED. Routine industrial hygiene and some environmental sampling, but no organized ecological program.
- 1945** Formal ecology program set up at Hanford in Quonset hut (Foster et al.). Pile effluents studied.
- 1946** Work begins on Columbia River itself. Joint Hanford–University of Washington operation.
- 1949** Concluded that Hanford reactors do not threaten fisheries resources or water supplies of Pacific Northwest, but work produces many surprises. Columbia River Advisory Group formed.
- 1950** Ecology program established at Oak Ridge, primarily around environmental contamination in and around White Oak Lake. Joint TVA–ORNL program (Krumholz et al., Struxness).
USPHS sends ecology team to join in Hanford work.
Term “radioecology” begins to be used.
- Early 1950s** Ecological work further broadened at Hanford. Terrestrial ecology program added.
Morgan and Struxness push for financing of Oak Ridge program.
Clinch River comes under study.
- 1950s** Development of ecological facets of operations at National Reactor Testing Station (Idaho Falls).
- 1951** Initial ecology studies at Savannah River site and of Savannah River (Odum at University of Georgia and Philadelphia Academy of Natural Sciences, respectively).
- 1952** Descriptions of Canadian ecological work around Chalk River Plant (Langford and Rigler).
- 1954** Start-up of Rocky Flats plant (Colorado) accompanied by environmental surveys.
- 1955** Stanley Auerbach joins Oak Ridge group.
Hanford work summarized at first Atoms for Peace Conference (Foster and Davis; Hanson and Kornberg; Parker).
Savannah River–University of Georgia collaborative work described at same conference (Odum).
- 1956** Analyses of doses from “cloud passage” (Holland; Snyder; Parker and Healy; Manley and Fry) given at first Atoms for Peace Conference.

(a) For abbreviations and acronyms, see Appendix D.

- 1956–1958** U.K. studies of Irish Sea off Windscale (Dunster). Priority of liverbread pathway established. Mobile laboratories used for terrestrial surveys around Windscale (Fair and McLean).
- 1957** NAS–NRC report on effects of atomic radiation on oceanography and fisheries.
Review of radioactivity in aquatic forms (Donaldson and Foster).
- October 1957** Windscale incident in U.K. Large amount of follow-up work.
- 1957, 1959** Brookhaven report on consequences of major reactor mishap. Report issued 1957 as WASH-740. Derived paper published 1959 in proceedings of second Atoms for Peace Conference (Kuper and Cowan).
- 1958** Healy et al. (Hanford) discuss routine radiation exposures in environs of a major atomic energy plant. Also wind dispersal of contaminants (Healy and Fuquay). Published 1959 in proceedings of second Atoms for Peace Conference.
Environmental Sciences Branch developed within AEC's Division of Biology and Medicine.
- 1959** Uranium mill tailings surveys enter Congressional hearings, e.g., Animas River in Colorado–New Mexico (work by Tsivoglou and others).
- 1960** Symposium on Radioisotopes in the Biosphere at University of Minnesota (Caldecott and Snyder, eds.). Cogent papers by Bustad, Hanson, Kornberg, Foster, Davis.
- 1960–1979** Fourteen IAEA symposia and seminars bearing on radioecology (listed in text).
- 1960s et seq.** Puerto Rico Nuclear Center studies marine ecology of radionuclides.
Woods Hole Oceanographic Institution enters field.
Scripps Institution of Oceanography mounts several projects at sea and in the laboratory.
USPHS involved to growing extent in terrestrial radioecology.
Ecosystem experiments (in contrast to surveys) begin.
Lawrence Livermore Laboratory joins the field.
Broad program of studies of high radiation background areas of Brazil and India (Eisenbud, NYU).
- 1961** First National Symposium on Radioecology, Colorado State University (Schultz and Klement, eds.).
- 1962** Permanent ecological facility and full-time staff developed at Savannah River.
Ringold Farms study begins at Hanford. Whole-body counting of population.
- 1963** Neal Hines's book *Proving Ground* published. First part reviews the ecological work at Hanford site and Columbia River.
First edition of M. Eisenbud's book *Environmental Radioactivity*.
Work reported from Chalk River, Canada (Ophel).
- 1964** NYU begins work on Hudson River estuary, especially in reference to Indian Point Power Plant (Wrenn, Jinks, Eisenbud).

- 1965** Hanford biology symposium on radiation and terrestrial ecosystems (Hungate, ed.).
- 1966** Stockholm symposium on radioecological concentration processes (Åberg and Hungate, eds.).
Polikarpov's book on aquatic radioecology (USSR); reviews a large amount of work including that in USSR and eastern Europe.
- 1967** Second National Symposium on Radioecology, Ann Arbor, Michigan (Nelson and Evans, eds.).
Publication of Clinch River study (Struxness et al., Oak Ridge).
- Late 1960s** Hanford produces master plan for radioecological research. Marine laboratory opened at Sequim, Washington.
- 1969 et seq.** USPHS work on tritium from nuclear power facilities.
- 1970** University of Minnesota symposium "Nuclear Power and the Public" has many environmental considerations (Foreman, ed.).
Colorado Committee for Environmental Information formed to follow up Rocky Flats contamination (Martell et al.). Reports extended throughout the 1970s.
Health Physics Society symposium on the siting of nuclear facilities (Idaho Falls).
Los Alamos designates a formal environmental studies group. Work divided between local sources of contamination and global fallout (more in chapter 12).
- 1970 et seq.** HASL deeply involved in Rocky Flats measurements and polemic (Krey, Hardy, et al.)
Argonne National Laboratory work on plutonium in the Great Lakes.
- 1971** Third National Radioecology Symposium, Oak Ridge (Nelson, ed.).
Symposium on environmental plutonium at Los Alamos.
Hanford symposium on transuranics includes much work on the environment; published in 1972.
- 1972** Bibliographic review of radioecology by Schultz and Whicker.
Studies of oysters in Pacific Northwest indicate contamination with radionuclides, but no demonstrable effects (Nelson et al.).
Book by Pruter and Alverson on Columbia River estuary published.
- 1973** Book, *Tritium*, edited by Moghissi and Carter, includes much work on environmental aspects.
WASH-1209 and WASH-1250, "The Year 2000," study published.
WASH-1258 environmental statement for light-water-cooled nuclear power reactors published.
Draft environmental impact statement for LMFBR published.
Review of published work on plutonium in the environment by Stannard.
Lawrence Livermore work begins on tritium in aquatic systems.
- 1974** WASH-1535 environmental impact statement for LMFBR.

- 1974 American Nuclear Society symposium on environmental levels of transuranium elements.
- 1975 WASH-1400 reactor safety study.
Fourth National Symposium on Radioecology, Oregon State University (Cushing et al., eds.).

Chapter 11

Survey of Radioecology: Environmental Studies Around Production Sites

Overview

This first chapter of these five devoted specifically to radionuclides in the environment presents both a brief survey of the field of radioecology and selected aspects of work directed primarily at the production sites. It is historically oriented, of course, and focuses attention on the earlier phases of development of the field. Nevertheless, it is possible, with the help of some excellent recent summaries, to give a reasonable, if capsulized, picture of the field in the early 1980s.

The chapter begins with the development during World War II of radiobiological research on aquatic life forms at the University of Washington Applied Fisheries Laboratory in Seattle and the exhaustive research on the Columbia River and its fisheries done by staff at both the University of Washington and the Hanford Works—all apropos the possible releases of radioactivity from the plutonium production reactors at Hanford. This was the beginning of radioecology. It was the only substantive work in the field during most of World War II.

Under the heading "The Early Postwar Years," the chapter examines the radioecological work in the years 1949 to approximately the mid-1960s. This includes the continuation and expansion of the work on the Columbia River and terrestrial studies at Hanford; the development of the White Oak Lake bed, Clinch River, and other studies at Oak Ridge; and a short review of the environmental studies at and around the Savannah River Plant. After considering these three major production sites, the chapter turns to descriptions of the problems and studies around uranium mill and refinery sites, reactor sites, fuel reprocessing sites, and the work of other U.S. government laboratories and universities. There is a brief review of some of the work done in Canada and the USSR and a fairly detailed description of U.K. activities, especially those around Windscale.

A special section is devoted to tracing the growth and maturation of the field of radioecology, both in the United States and abroad. This is done primarily by reviewing the major U.S. symposia on radioecology, the numerous international seminars and symposia sponsored by the International Atomic Energy Agency

and its collaborator organizations, and more current reviews and books. It is concluded that radioecology has indeed "come of age."

In a section labeled "The Later Years Around the Production Sites," many of the more recent extensions of work at the laboratories discussed earlier are described, plus short reviews of many of the newer entries into the field. This is organized partly around sites where problems arose and partly around the laboratories hosting the work. Here the opportunity is taken to make generalizations where possible and appropriate.

The last major section brings together a miscellaneous group of environmental subjects that required some exposition either as part of the general survey of the field or to introduce still other site-oriented topics. This section includes discussion of the Liquid Metal Fast Breeder Reactor Program and a little more about nuclear power reactors. It discusses the role of the environmental impact statement in furthering the field. It also gives very broad general discussions of marine radioecology, transuranics in the environment, and tritium in the environment. In each case, much of the information is transmitted by citing the contents of important symposia and other publications.

The chapter closes with a short commentary on the material presented.

To aid the reader in following the development of the field and in finding further details, the contents of several of the major symposia and other publications are placed as "notes" at the end of the reference section. Also, the chapter quotes rather liberally from sources that have produced useful and moderately comprehensive generalizations.

I. Introduction

In order to discuss work done around the sites, we will need to introduce some general aspects of radioecology as we go. For this reason, the chapter is labeled as a "survey" as well as a discussion of environmental studies around production sites.

Concern for the possible results of contamination of the environment around sites connected with nuclear energy activities arose very early in the operations. During the years of the Manhattan Engineer District (MED), much of the work was perforce confined to environmental measurements of releases using prevailing industrial hygiene approaches. The MED plants were, in general, too busy with new tasks to give more than average attention to potential environmental problems. They were probably as good neighbors as most industrial plants, but the practices we now take for granted were still to be developed, much less applied to the environment. An outstanding exception to this was the Hanford operation, as we will see in the next section.

The end of World War II and the lifting of security restrictions brought a rising tide of both investigational and surveillance-type work directed at the environments surrounding the production sites in operation, and the planned new facilities. Gradually the work became less oriented toward the particular site and took on an identity of its own as bona fide research with broad objectives. Some installations became centers for the new field of "radioecology" and continue to be so. Environmental concerns played an ever increasing role in all phases of the enterprise so that now they are paramount.

We will emphasize the genesis of the work and the shaping of its primary investigational lines and let the excellent reviews, symposia, and books fill in the details, especially for more recently developed aspects.

II. The Years of World War II: Hanford and Seattle

When it was decided to place the huge production reactors on the Columbia River at the Hanford site, questions arose immediately about their possible environmental impact. After all, the Columbia and its tributaries supplied drinking water for hundreds of communities. Moreover, the fisheries industries of the Pacific Northwest supplied food for millions of people and were a natural resource of first-order importance.

Stafford Warren, the indomitable medical director of the Manhattan Engineer District raised questions about the impact of the Plutonium Project on the Columbia River only a few months after the decision was made to locate the production reactors on its banks. Ground was broken for Hanford on April 6, 1943. Pile construction began on June 7, 1943. On May 20, 1943, Warren started activities aimed toward the broad biomedical and ecological problems.^(a)

It was realized that very little was known about the radiosensitivity of aquatic forms of life. It was suspected that even if adult forms were not more sensitive than terrestrial forms at the same level of phylogenetic development, the possible sensitivity of developing eggs and embryos might be critical to the entire life cycle of salmon and trout, as well as other aquatic forms. Importantly, the spawning and breeding grounds of these species were all along the shores and embayments of the Columbia River; some of them hard by or closely downstream from the reactor sites. Knowledge of the radiosensitivity of all stages of their development was essential.

Neal Hines (1962) tells of the fortunate presence and willingness to serve of Lauren Donaldson at the Applied Fisheries Laboratory of the University of Washington in Seattle and the recruitment of Richard F. Foster, who had just completed a Ph.D. thesis on the effects of ionizing radiation on rainbow trout, and of Arthur Welander who had done likewise with chinook salmon. These, plus Kelshaw Bonham and somewhat later Allyn H. Seymour, formed the nucleus of a group of remarkable productivity and stability.^(b)

The first contract was between the University of Washington and the U.S. Office of Scientific Research and Development. No possible connection between the radiation studies they were about to undertake and the construction work at Hanford could be permitted.^(c) Thus, no association with the MED could be countenanced. The contract was let on August 15, 1943. Work with x rays on embryos, larvae, and fingerlings as well as adult salmon, and later trout, began as soon as equipment could be installed.^(d)

The work on immature stages of fish indicated what we now know well—greater sensitivity to radiation than for adults of the same species. However, the sensitivities were not so different from those of terrestrial forms of life as to

(a) These and many other details can be gleaned from chapter 1 of the beautifully written and authoritative documentary book by Neal Hines entitled *Proving Ground* (Hines 1962) and the equally attractive chapter by Foster in a later book that brings together in depth the tremendous efforts expended on the potential problems of the Columbia River and its estuary (Foster 1972).

(b) They are still producing despite theoretical retirements.

(c) It was fortunate indeed that Foster and Welander had already been interested in the effects of radiation on fish. Not only were they prepared, but the new work could be easily viewed as an extension of their former interests.

(d) Hines tells that Francis Bishop, a key radiological technician from the University of Rochester, came to Seattle to help install the x-ray equipment in a hurry.

predict cataclysmic effects on the fish population. There did seem to be somewhat more delay in the expression of the effects in the aquatic forms, possibly because of the lower body temperatures in general. While much of the work with adults utilized fairly high doses, the really interesting work involved low and moderate doses. Such doses were given to young adult fish that would go to sea for two years or more. It was the effect on the numbers and health of the fish returning to spawn that was the key question. Such work was possible because of the remarkable homing instinct of salmon to spawn in the same place, *exactly*, that they left to go to sea.

However, the answers to these questions were at least two years away. The effects of Hanford pile effluents needed immediate attention. Thus, the venue for this exposition shifts from Seattle to the Hanford site^(a) and from x rays to pile effluents. In early 1945, Foster was moved to Hanford and set up in a Quonset hutment near one of the reactors. This was called the Fisheries Laboratory and was built as sort of a swan song by some of the construction workers finishing off the adjacent reactor complex. It is pictured in figure 11.1.

Two types of work proceeded at this facility: (1) exposure of fingerlings to various concentrations of pile effluents in troughs reminiscent of fish hatcheries the country over to measure possible deleterious effects, and (2) the uptake and retention by the fish of radionuclides from the pile effluent stream. In addition, studies were begun in 1946 on the river itself—its fish, the plankton, the dilution

FIGURE 11.1. The Fisheries Laboratory (Building 146-F) at the Hanford plant during the MED days. (Photograph courtesy of Pacific Northwest Laboratory.)

(a) The continuing x-ray work at the Applied Fisheries Laboratory is nicely summarized by Hines and by Foster. Indeed, Hines gives a complete listing of the University of Washington Fisheries Laboratory reports (UWFL series). This work is somewhat outside of our purview because it did not use radioactive materials, and we must forego the impulse to describe it in detail. It was absolutely basic to the whole enterprise and expertly done.

and distribution downstream of the effluents, effects of the warm water from the reactor on the temperature of the river, and gradually the entire aquatic ecosystem.

The story of this research is available in depth in the chapters by Hines and by Foster and in the literature cited therein. "By 1949 the laboratory and river studies at Hanford had shown that the fisheries resources of the Columbia River were not threatened by the plutonium plant and that there was no radiation hazard to people who used the river and its fish" (Foster 1972, p. 8). Indeed, process chemicals in the reactor effluent, such as sodium dichromate, showed greater potential toxicity to aquatic life than the amounts of radionuclides discharged. Only a factor of ten separated the usual concentrations of these in the river near the piles and known toxic levels.

There were some surprises, however (Foster 1979). At the beginning, only gross radioactivities were measured. Separation of isotopes was not yet routine. As techniques developed for identifying radioactive materials, it became apparent that those present in the river were largely products of neutron activation of substances already present in the river water and components of the pile structures. However, there were more fission products present than any reasonable prediction of fuel element leakage would support. Also, the concentrations were more or less constant, not released in puffs as would be expected from occasional leaks in the fuel elements. This turned out to be due to activation of "tramp uranium" already present in the river water.

Another surprise was that the activity in fish from the river was substantially greater than that in fish from the laboratory exposed to pile effluents. This puzzler was explained by the fact that the laboratory fish were being fed uncontaminated food, whereas the river fish got their food from natural sources that contained normal radioactivity (not increased much by the reactors). This led to the elucidation of the importance of the food chain and of concentration in organisms of some of the elements by specific metabolic processes.

Yet another surprise was the finding of a qualitative difference in the elements in laboratory versus river fish. The radioactivity of laboratory fish came from elements like sodium and other short-lived materials that were easily assimilated from the surrounding water. By contrast, the fish from the river showed high concentrations of substances like ^{32}P , which had been concentrated from nutrients. Thus, again the importance of metabolic processes in concentrating radionuclides from the environment and of the food chain was highlighted.

Another finding that was not fully expected was the presence of sufficient amounts of ^{51}Cr to have it present, indeed predominant, at the mouth of the Columbia. As remarked earlier, sodium dichromate was added to the intake water of the reactors as an algicide. Activation of the stable chromium in the neutron flux of the reactors generated the ^{51}Cr . Even so, it was the nonactivated stable chromium in the released sodium dichromate that posed the principal immediate toxic hazard to aquatic life of the Columbia River.

In essence, the war work gave clear answers to the original question—toxicity of the pile effluents^(a) in the short term. However, the need for measurement

(a) We should add that back at Seattle the salmon that had received low radiation doses before going to sea were now returning in numbers and were in no worse shape than nonirradiated cohorts after two years of buffeting in the fierce marine environment.

of more subtle long-term effects was apparent. Also, the behavior of radionuclides in aquatic environments was only beginning to show its potential ramifications. It is not surprising, therefore, that more permanent facilities and long-term staff commitments developed at both Hanford and Seattle after the war, as we shall see in the next section.

The Hanford ecology effort during World War II was not confined to aquatic biology. As related in earlier chapters, it was known that radionuclides such as radioiodine and radioruthenium were being released in small but measurable quantities from the facilities. Radioiodine was easily found in the thyroid of jack rabbits on the site. However, there was concern over the cattle in the environs of the plant, especially some that were on the opposite side of the Columbia. How could some measurements be made without breaking the tight security as to what was going on at the plant? A graphic description of how one set of measurements was made is contained in the following excerpt from a communication sent to this author by Karl Herde:^(a)

In the summer of 1946 several herds of cattle frequently were seen grazing on AEC property [sic] across the river from Hanford reactors and separations plants on land generally known as the Wahluke Slope. Iodine-131 releases were not at that early date well controlled and were known to have resulted in significant concentrations in rabbits, goats and sheep on the plant site. Concentrations in the thyroids of Wahluke Slope cattle were unknown and a challenge to those responsible for monitoring.

The Manhattan Engineering District Manager was asked to cooperate in making a survey possible. A request for volunteers was sent down the line through the U.S. Army Component then stationed at Camp Hanford. Six volunteers selected because of "special western ranch experiences" reported to the writer in a jeep and two 4-wheel drive weapons carriers at the Hanford Ferry early one July morning. Each vehicle had a 50-foot length of new manila rope that was to be used for lariats and at least two of the G.I. volunteers wore cowboy boots and ten-gallon hats to prove their "suitability" for this special job.

After crossing the Hanford Ferry the fleet of three vehicles journeyed along the river past several abandoned farm sites before taking trails that led to the slope where a herd had been spotted. Two vehicles carried "Pfc cow-pokes" with coiled lassoes. The other carried biologists with a primitive portable geiger counter. At the first approach the herd showed little alarm, the two "ropers" agreed to cast their ropes simultaneously at two big steers near the outside. The ropes fell short by about one third the distance and the cattle stampeded. Each vehicle pursued a dogie and a long dusty chase began. Time after time lariats missed target. It was obvious that no special talent was riding the range. After the humiliation of many failures, and the slowing down of the dogies the ropers tried bull-dogging. As the animal was ready to fall from exhaustion the "bulldoggers" plunged victoriously upon it, slipped a rope over its head with a half-hitch on a foot, and stood triumphantly over the wheezing prize.

External thyroid counts being surprisingly low and observing no physical injury to animals, the team was asked to capture and monitor another pair from this herd.

A second herd located further west in the vicinity of White Bluff was similarly "scientifically sampled." Fortunately in neither case did we encounter owners of the herds. Since this was off-limits, the farmers were content to let the cattle drift out unattended. We suspected that the ranchers deliberately scheduled their round-ups of the herds during the dark hours. Though somewhat higher in thyroid

(a) Karl Herde was among the early workers in the Hanford group and the first professional biologist assigned to the Biology Group. He later went to Savannah River from which he is now retired. I am indebted to him for these anecdotal descriptions.

readings, the levels monitored were calculated to be of no health hazard to the cattle nor to persons handling the animals or consuming the meat. Several vegetation samples were collected from each location in order to facilitate a comparison between the food consumed and thyroid activity.

In a conference to evaluate and analyze the thyroid data no special concern was felt for the animals of Wahluke Slope nor their owners who lived beyond the crest of Saddle Mountains or on the plateau to the east. However, it focused attention on other areas. The prevailing winds were favorable to the Slope, but what about the more populated and intensely farmed valley of the Yakima River? Smaller farm herds from the irrigated area from Toppenish to Benton City should be monitored and this could not be accomplished as completely secretive as we had monitored animals of the Wahluke Slope. This need was passed on to the Security Division of the Manhattan Engineering District and became another historic venture in biological monitoring, that is the subject of another episode report.

The Wahluke Slope monitoring produced no striking results but was a positive factor in selling the needs for an experimental animal farm that became a reality at the 100-F Area in 1948. (Herde 1978)

It took a more subtle approach to get data on thyroid activity from cattle in the Yakima River valley mentioned by Herde in the quotation above. Excerpts from his description of that operation are given below:

Though the Environmental Survey Group at Hanford had been sampling air, soil, water, and vegetation in a wide area surrounding the Hanford site for several years previous to 1946, it was agreed that sampling farm animals for uptake of fission product plant wastes would be a much more sensitive problem. At that time the revelation of a regional iodine-131 problem would have had a tremendous public relations impact and furthermore the presence of other nuclides (some known but some not recognized or identified) was of possible National Defense significance.

I was called at my home before work hours and asked to report, not to my area office, but to the Director's office in downtown Richland, for instructions upon a full day's trip off the site. I was advised to dress in field clothing, preferably khaki shirt and pants, a tie and leather jacket. Once in the Headquarter's Office I was introduced to two Security Agents of the Manhattan Engineering District (MED) who were to be my escorts and contact men during the day. They proved to be the best straight-faced "liars" I had ever known. I was no longer "Karl Herde of Du Pont" but through that day would be known and introduced as Dr. George Herd, of the U.S. Department of Agriculture. I was to simulate an Animal Husbandry specialist who had the responsibility of testing a new portable instrument based on an unproven theory that by external readings on the surface of farm animals the "health and vigor" of animals could be evaluated. I was advised not to be alarmed if at times during conversations with farmers that they appeared critical or skeptical. I was to be very reserved and answer questions as briefly and as vaguely as seemed acceptable. They agreed to carry a clip board to write down essential data on the location, size of herds, approximate age of animals, and general comments. I was to concentrate upon the high readings (thyroids, of course) and furnish those for recording when not being observed.

That day we visited several diversified farms under irrigation from the Yakima River between Toppenish and Benton City. Livestock observed and monitored included horses, cattle, and sheep. Smooth talk and flattery enabled us to gain one hundred percent cooperation. Farmers were most interested in measuring the sire of the herd. Ironically to me, the thyroid activities of these were usually lower than average due to increased confinement upon a regimen of dry feeding.

Animals were either run into stocks or stanchions or were haltered and tied during the survey. Numerous measurements were made, usually in the flanks, scrotum, udder, and neck with "emphasis on the jugular vein." While "measuring the jugular" I was successful in placing the probe of the instrument directly over

the thyroid at times when the owner's attention was focused on the next animal or some concocted distraction.

This clandestine monitoring was possible at that time only because of the general secrecy that still prevailed around the atomic energy program. (Note the use of lower case, as there was no Atomic Energy Commission at that time.) The geiger-counter was known to professional physicists but did not become a household word until several years later when prospecting for uranium and measuring fallout from weapons testing made it famous.

Instruments used at Hanford were intentionally named to be misleading lest they be associated with the product or the mission of the site. The instrument used was called a "G.M. Counter," but on that particular day it was called the "thing," "your gadget," or your "brain-child" as if my colleagues were skeptical. It may be of interest to recall that during the war an instrument specialist had developed a new "sniffing instrument" for which he proposed the name Pluto, in honor of Pluto the Pup, a cartoon character. General Leslie Groves of MED censored the name since it might suggest plutonium as a product of this highly secretive plant.

Positive, though low thyroid readings in nearly every animal examined helped establish the basis for an experimental animal farm which was planned and sold by the writer and colleagues and built in 1948 at 100-F Area.

At the Experimental Animal Farm the health significance of various intakes of iodine-131 and its subsequent accumulation in thyroids was evaluated for sheep, cattle, and swine [chapter 8]. Based upon that research and such biological monitoring as reported above we were able to say that it is very unlikely that animals or persons consuming milk and meat products grown in the vicinity of Hanford were in any case damaged. (Herde 1978)

Before we leave the years of World War II, we should be reminded that the Metallurgical Laboratory at Chicago did some work on the uptake of fission products by goldfish (see chapter 7, work by C. L. Prosser et al.). The distribution was quite like that seen in terrestrial mammals.^(a)

III. The Early Postwar Years

A. Continuation of Hanford Work

Unlike the major changes wrought at many of the MED laboratories by the transition from wartime to peacetime endeavors, most programs at Hanford continued almost without a pause. Even the transition from the Du Pont Company to the General Electric Company as prime contractor made little immediate difference in programs. This was especially true of the environmental biology work. True, the investigators now knew why they were doing the work, and the gradual lifting of security restrictions allowed much more communication among segments of the enterprise, particularly between Hanford and the University of Washington. The primary change was an increase in effort and momentum.

The very first annual report of biology research^(b), covering the year 1951 and published in April 1952 (Hanford Works 1952), contained the following summary

- (a) At the time of review of this work in chapter 7, we wondered if the Met Lab people did this out of idle curiosity or for other reasons. Since we have now seen the depth of interest of Stafford Warren and others in fisheries problems, we might conclude that the goldfish work was more than idle curiosity.
- (b) The biology section of the report contained programs on aquatic biology, metabolism of radionuclides, toxicology, and biological services as part of the Radiological Sciences Department.

by R. F. Foster of work on the biological problems associated with the discharge of pile effluent into the Columbia River:

The location of the Hanford Works on the banks of the Columbia River has raised many questions of possible effect on the aquatic life. Such questions were initially prompted by concern for the economically valuable salmon and other fisheries resources supported by the Columbia and by concern for the hazard which might result from utilizing local game fish as food. To answer some of these, an aquatic biology laboratory was established soon after operations were started, and from this beginning an integrated program of research on organisms of the Columbia River developed.

Large volumes of Columbia River water passed through the nuclear reactors as coolant are ultimately returned to the river. This pile cooling water, or effluent, constitutes a potential hazard to aquatic life since it is hot, mildly radioactive, and contains certain toxic chemicals. Investigation of the actual or potential effect of this effluent on the biota of the Columbia River is the principal objective of the Aquatic Biology Unit, and basic approaches involve both laboratory experiments and field observations.

One group of laboratory studies is designed to determine the dilution level at which adverse effects are first apparent, and further whether such effects are due to radioactivity, chemical toxicity, temperature, or some combination of these factors. Since operating conditions for the reactors are subject to change and since irregularities could occur at any time which might increase the hazard to aquatic forms, subjection of organisms to dilution of the pile effluent is continued throughout the year and from one year to the next as a type of biological monitoring. Young salmon and trout are used as test animals for these studies since they represent species of economic value and also appear to be among the forms most sensitive to the effluent water. The chinook salmon are of particular interest since a substantial portion of the fall run of this species spawns in this section of the river.

It is not possible under laboratory conditions to duplicate or even closely approach all of the environmental factors present in the river, and many complex and delicate ecological relationships and balances are in operation which conceivably could be affected by the effluent. Field studies were therefore undertaken in order to determine the natural ecology of the river and the biological conditions of that section of the river which receives effluent from the pile areas. These studies include: (a) comparing such characteristics of the aquatic communities as species abundance above and below the effluent outlets, (b) determining seasonal variations in these communities and (c) determining various interspecific relationships such as food chains. Associated with the ecological studies, radioactivity measurements are taken of the various river organisms. From these measurements it is possible to determine which isotopes present in the pile effluent are concentrated in the river organisms in significant amounts, which organisms become most radioactive, the distribution pattern of the radioactivity in the river, the seasonal fluctuations and their significance, whether the organisms are receiving radiation that may affect them or their progeny, and the extent of the hazard to humans utilizing river fish for food.

Certain isotopes present in the effluent water, notably P^{32} , are substantially concentrated in the aquatic forms of the river. This concentration is responsible for the greatest part of the potential radiation hazard, and adequate knowledge of the mechanism of this concentration is desirable in order to permit a rational approach to its control. While the plants concentrate radioactive isotopes directly from the surrounding water, the higher animals obtain these isotopes not so much from the water as from the lower forms upon which they feed. Thus the food chain is of prime importance in determining the ultimate levels of activity density attained by the higher organisms, including the fish. The susceptibility of the lower forms of life to the pile effluent takes on added significance in view of their role of sustaining

the economically valuable species. The determination of the rates at which representative forms pick up radioactivity from the environment, the importance of various types of food organisms in accumulating and transferring the radioactive materials, the levels to which specific isotopes become concentrated in the organisms, and the rates of elimination of radioactivity or biological turnover, constitute another area of research to which some attention has been given and from which we may hope to gain suitable explanations for observed levels of radioactivity in the river biota. (Foster 1952)

This summary is followed by details on spawning and migration of Chinook salmon in the river in the vicinity of Hanford, radioactivity of aquatic organisms, transfer of pile effluent to trout, effects of pile effluent on fish, etc.^(a) A graph from this early report showing the geographical distribution of radioactivity in snails from various sections of the river is shown as figure 11.2.

FIGURE 11.2. Geographical distribution of "radiation density" in snails sampled during September 1952. (Redrawn from Davis et al. 1952.)

In this first annual report, we are also made aware that a sizable program of terrestrial ecology was under way.^(b) It was hidden away under the broad title, "Biological Monitoring" (Hanson and Browning 1952) and concerned the ^{131}I in the thyroid tissues of jack rabbits collected near the separations plants and radioactivity in ducks maintained at a disposal ditch containing fission products. The most interesting finding was that the concentration of fission products in

(a) The earliest reports were in the classified HW series and bear the names of Herde, Coopey, Davis, Palmer, Watson, Honstead, and others. Some of these are cited by Foster in his introduction to the Pruter-Alverson volume (1972). See, for example, Davis et al. 1952. Others, such as J. Corley and J. Soldat appeared as the work progressed.

(b) In chapters 8 and 9, we learned that iodine from the plant sites was one of the first airborne contaminants identified, and that ruthenium particles led to the first concern about the inhalation of "hot particles."

bone of the ducks was from 102 to 105 times that of the water, no surprise now, but it impressed the early investigators. The report cites originally secret documents by Herde, Cline, Hanson, and Browning.

At the first International Conference on the Peaceful Uses of Atomic Energy (held in Geneva, Switzerland, in 1955 [proceedings published in 1956]) Foster and Davis summarized work on the accumulation of radioactive substances in aquatic forms; Hanson and Kornberg discussed radioactivity in terrestrial animals near the site; Rediske and Hungate described the absorption of fission products by plants; and Parker gave a general review of radiation exposure from environmental sources.

The first-named review (Foster and Davis 1956) showed that radioactivity (called "radioactivity density") could vary by an order of magnitude in plankton versus fish; that the aquatic plants picked up substantial quantities by adsorption on their extensive surfaces; that scales of fish contained the highest concentrations followed by bone, liver, kidney, etc., just as in terrestrial organisms; and that the concentrations in plankton and other organisms decreased rapidly with distance from Hanford, as was shown for snails in figure 11.2.

The second-named review (Hanson and Kornberg 1956) showed ratios of ^{32}P in adults, eggs, and young of birds and the sometimes high but quite variable ratio of amount in bird to amount in water and that the amounts deposited had no effect on hatchability of eggs or fertility of adults. They also gave a breakdown of the isotope composition of swamp water, vegetation, bird muscle, and bird bone (they differed markedly). They reported that relative ^{131}I concentrations could range from 100 in rabbit thyroid to 20 in coyotes to 1 in insects and 0.2 in vegetation, the latter two considered as staple food items for the animals studied.

The Parker paper (Parker 1956) presented a capsule classification of the hazards that could be expected around various types of reactors, around chemical processing plants, and potential exposure mechanisms. While brief, even cryptic, this exposition is remarkably prescient and complete. It gives a glimpse of the fact that even in the early postwar years the groundwork had been laid for most of what followed. This included air, water, vegetation, animal, and aquatic biota sampling, as well as the encouragement of research under controlled laboratory and environmental conditions. H. M. Parker was behind all of it.

During these years (decade of the 1950s), the Hanford crew did much of the work, even rather distant from the site without a great deal of collaborative help except from the University of Washington Applied Fisheries Laboratory. Representatives of various state and government agencies were invited in to see what had been going on during the war and what was under way at the time. This occurred in 1945 and 1946, soon after the lid of secrecy had been partially sprung (Foster 1972). There was a Columbia River Advisory Group established by the Atomic Energy Commission (AEC) in 1949 to "provide advice and program direction and waste disposal procedures." This included appropriate state agencies of Oregon and Washington and the regional office of the U.S. Public Health Service (PHS). It met periodically over a period of fifteen years or so.

In 1950, the Public Health Service sent an ecology team to Hanford. They worked for about two years and amply confirmed the major findings of the Hanford people (see Robeck, Henderson, and Palange 1954). Nevertheless, the bulk of the work was conceived and implemented from Hanford and the University of Washington.

On the occasion of a personal visit to Hanford during the 1950s, it was this author's privilege to see both the laboratory and field work, albeit somewhat superficially. He met the crew and saw the thirty-foot biology boat fitted out with many special home-built devices for controlled water sampling and other activities. This palatial craft is pictured in figure 11.3, courtesy of J. Soldat and his capacious files.

FIGURE 11.3. Biology boat used for sampling in Columbia River in early days (courtesy of J. Soldat, Pacific Northwest Laboratory [PNL]).

The work of this and similar craft and crews led to the clear identification of radioactive materials from the Hanford site not only in the Columbia River estuary, but in the Pacific Ocean far beyond the mouth of the river. Description of these findings will await our discussion of the later postwar years.

A different aspect of the Hanford early postwar work was displayed at the second Atoms for Peace Conference. This was held in Geneva, Switzerland, in 1958. Healy and coworkers presented what was probably the first publication intended for a broad audience on the potential radiation exposure of people in the environs of a major atomic energy plant,^(a) viz., Hanford (Healy et al. 1959). The estimates of dosage were made for the year 1957, a year when fallout from nuclear weapons tests was significant, but the authors were able to "correct" for this. The chief caveat in this early report concerning a production site was that

(a) There were others, but these were theoretical analyses of possible reactor accidents (e.g., Kuper and Cowan 1959). These are not our subject here.

the operations were not representative of the nuclear power plants of later years. The reactors used once-through water cooling, and there were large chemical separations plants on the site also.

They developed what we would now call a source term from data on releases; they measured air concentrations, vegetation contamination, etc.; they measured concentrations in river and drinking water and in food such as whitefish flesh^(a) and edible duck flesh; they identified isotopes from irrigated land and in the river water; they followed variations with time of the year; and they presented the results as percentage of maximum permissible limits. The data included bone, thyroid, gastrointestinal tract, and gonads. The only values that were above (slightly) the then-permitted population limit occurred in the gastrointestinal tract at the perimeter of the plant site in June and October and at a distance greater than 60 km, also in October. However, many of the other values for gastrointestinal-tract exposure were appreciable fractions of the population limit. The final values calculated for total exposure to internal emitters from several sources is shown in table 11.1:

TABLE 11.1. Total Exposures at Plant Perimeter (Hanford) from Internal Emitters—Percentage of Maximum Permissible Limits.

	Bone	Thyroid	GI	Lungs
Drinking Water	3	2	20	—
Air	—	0.03	—	0.1
Vegetation	2*	3	40*	—
Fish	20†	—	6†	—
Waterfowl	25†	—	8†	—

*Excluding Sr⁹⁰; remainder primarily from nuclear detonations.

†Maximum to very small portion of population.

Note: Strontium-90 was omitted because of variability in its contribution. Bone samples indicated accumulation of less than 1% of the maximum permissible.

At this same Geneva Conference, we get a glimpse of another Hanford interest: dispersion of contamination by wind (Healy and Fuquay 1959). This is of special concern in arid regions such as Hanford and the Nevada Test Site (NTS) and will be discussed in connection with the "safety tests" (chapter 14) and environmental transport (chapter 15).

Leo Bustad, whose work with iodine we met in chapter 8, gave a succinct review of Hanford work in relation to animal populations in the environment at a symposium on radioisotopes in the biosphere (Bustad 1960). He showed the concentrations of eleven isotopes in fish, ⁶⁵Zn concentration in a beef cow, accumulation of radioisotopes from drinking water by rats, and the concentrations and behavior of iodine. He tied this information to the ongoing

(a) Richard (Dick) Foster, whom we have already met as director of the Hanford aquatic biology operation, is reported to have routinely eaten, each Friday night, at least eight ounces of whitefish caught in the Columbia near Hanford. Later, when whole-body counting became common, he was a regular and willing subject. So far as this author knows, his count always remained within normal limits.

animal-farm experiments, considered the Hanford plant's limits for population exposure, and concluded that the population exposures were "inconsequential."

A cogent chapter in the same symposium by Hanson, which drew also upon Hanford experiences, concerned iodine in the environment (Hanson 1963). This covered nearly every aspect of iodine in the environment and showed how far along the field was even in the early 1960s. It included information on the effects of iodine as well as its transport.

At the same meeting, Harry Kornberg, manager of the Hanford biology operation, presented work on the passage of pairs of elements through food chains. We will have much occasion to review the data and concepts developed on this subject when we review fallout and experimental work arising out of the fallout problems (chapter 13).

A later review by Foster on environmental behavior of chromium and neptunium revealed yet another facet of the work at Hanford (Foster 1963). Also, J. J. Davis discussed the relationships between cesium and potassium (Davis 1963). These, like the other papers in the session, were broad reviews of the subject, but drew their illustrations from the information gathered in Hanford work.

A comprehensive summary on the Columbia River estuary is given in the book by Pruter and Alverson (1972). This work was the result of studies suggested by Gene Wallen in the Ecology Branch of the AEC Headquarters Division of Biology and Medicine directed by John Wolfe. Also, the Oregon Board of Health coordinated a series of whole-body counts on residents of a community on the Oregon Coast near the mouth of the Columbia River. These individuals were largely fishermen, seafood processors, and avid consumers of seafood. Their whole-body counts remained within the range of those associated with fallout radionuclides.

Obviously, by the end of the first decade plus a few years after the end of World War II, radioecology was beginning to prosper, and one of its prime centers was the Hanford Atomic Products Operation.

B. Enter Oak Ridge^(a)

Except for routine industrial-hygiene-type practices, expanded to include measurements of air and waterborne radioactivity, the Clinton Laboratories had no research program during the war years directed primarily at environmental concerns. Their waste disposal practices of the MED days involved largely impoundments and basins that were not lined with concrete or otherwise isolated from the environment except for high fences. In the early postwar years, Karl Z. Morgan, director of the Health Physics Division of Oak Ridge National Laboratory (ORNL), became increasingly concerned about the potential for release of contamination to the environment from these and its possible impact. The largest single impoundment was White Oak Lake, which was developed by placing a dam across White Oak Creek. It had received radioactive waste throughout the war years.

(a) Much of the information used in this description of the earlier days of the Oak Ridge ecology program comes from a taped interview with Stanley Auerbach, chief of the Environmental Sciences Division, Oak Ridge National Laboratory (Auerbach 1979) and the introduction and historical perspective to the excellent, two-volume book by Ward Whicker and Vincent Schultz (Whicker and Schultz 1982).

The first step was collaborative work with ecologically trained biologists from the Tennessee Valley Authority (TVA). One of these was a fisheries biologist, L. A. Krumholz, who has remained identified with radioecology ever since. Others taking part were a botanist, Nease, and two limnologists, Ross and Helm. The program was established in 1950, developed some momentum, and completed several ORO^(a) reports on several aspects of the flora and fauna and on the concentrations and behavior of contaminating radionuclides in White Oak Lake and its environs.

The group found ample amounts of radioactivity, identified many of the isotopes, and made a start on measuring their behavior in the environment. They could find no evidence of deleterious effects on aquatic or terrestrial populations. This led many segments of management to conclude all was well and that the work could be phased out. After all, this was a fairly highly contaminated area. A further factor was the presence of wide variations in results of work attempting to measure the impact of low-level radiation on the site, even the behavior of the radionuclides themselves. The presence of multiple factors characteristic of environmental work and the remarkable ability of complex ecosystems to accommodate to perturbations made for much of this variability. It did not surprise the ecologists, but it struck horror in the minds of physicists, chemists, and mathematicians who constituted a very influential force at Oak Ridge National Laboratory.

Several events occurred, however, that saved the Oak Ridge environmental program from obliteration. First, Karl Morgan mounted a crusade for continuation of the work. In his mind the real science lay ahead. He emphasized that what had been done so far was only preliminary and range-finding in nature. Second, it was decided to drain White Oak Lake! This was due to concern that a several-inch downpour of rain, not unknown in that part of the country, might cause the impoundment to overflow, even carry away the dam. Hence, the former lake bed was to become a meadow with a meandering stream and a dam that could be closed for flood-control purposes. Here was a natural contaminated ecosystem fully ripe for detailed investigation.

A third factor was the presence in high echelons of Eugene Wigner and others who had keen interests in the future of nuclear power and knew that radioactive waste disposal would be a key problem in any such development. Morgan persuaded management to transfer Edward Struxness, who was supervisor of health physics at the Y-12 plant, to the Health Physics Division of the laboratory to begin some scientific work on waste-management problems. Struxness, like Morgan, had considerable empathy for the environment. He had taken ecology courses during the war years and after. To him, "improving the waste management programs" meant research on and in the environment.

Soon Dr. Orlando Park, professor of ecology at Northwestern University who had taught Struxness, was brought in as a consultant and helped to map out the program. In 1954, Stanley Auerbach, who had done his Ph.D. work with Park, was persuaded to join the fledgling group. In 1965, a budget for 1.7 man-years (\$56,000) was earmarked for the program.

It was not out of the woods, however. Ecology was a strange subject to many of the good people at AEC Headquarters. They could see the need for large biology programs of more conventional nature as described in earlier chapters of this book, even the "megamouse" genetics program, but not the utility of a

(a) ORO = Oak Ridge Operations Office.

broadly based ecology enterprise. The idea was still widely held that if man was acceptably protected, his environment would automatically be protected. The fact that man is "an integral part of his environment" (Whicker and Schultz 1982, p. 5) had not yet become generally appreciated.^(a)

Both Auerbach and Whicker and Schultz indicate that much of the further development of radioecology at Oak Ridge and in the United States, generally beyond the programs already under way, was "due to the farsighted vision and encouragement of Charles Dunham (M.D.) who became chief of the Division of Biology and Medicine (DBM) of AEC in 1955" (Whicker and Schultz 1982, p. 6). By 1958, an Environmental Sciences Branch was developed within the DBM, and the capable Dr. John Wolfe, an ecologist from Ohio State University who had helped the DBM as a consultant, was persuaded to assume its direction. From this point on, funding for environmental aspects ceased to be a constant battle. In fiscal year 1970, the budget was \$18.9 million, divided into \$6 million for terrestrial and fresh water ecology, \$4 million for marine sciences, and \$8.9 million for atmospheric radioactivity and fallout (Whicker and Schultz 1982, p. 6). Only the first category helped to support the Oak Ridge program, of course.^(b)

A further stimulus was the finding of an osteogenic sarcoma in a muskrat with a heavy body burden of ^{90}Sr caught in the White Oak Lake area.

The first serious work in the revitalized Oak Ridge program was much more than an extension of the earlier TVA-ORNL collaborative effort. The White Oak Lake site gave an opportunity to address key questions of considerable ecological importance but of great technical difficulty. White Oak Lake had been drained, and the environmental group began probing the behavior of the principal isotopes in the old lake bed, e.g., ^{90}Sr , ^{137}Cs , ^{60}Co , and ^{106}Ru . Also, the several waste pits were known to be leaking, and the environmental sciences section decided to see to what extent trees might act as accumulators of the various isotopes. Because of lack of information on the underground hydrology, the results were again difficult to interpret. Some trees were "hot," others were not. There followed much work on the transfer systems, especially food chains in the lake bed and other areas. Also, they began inoculating trees with known doses of isotopes. Transfer coefficients and food chain components were identified from this work. A picture of the inoculating procedure is shown in figure 11.4.

In the 1960s, Auerbach and his growing group considered that a real ecosystem experiment could be started. They chose ^{137}Cs because it was in both fallout and nuclear plant waste and had mobility, convenient half-life, etc. They chose the tulip poplar because it is a common and important tree in the southeast. They inoculated a stand of these with 500 mCi of ^{137}Cs proportioned among the trees according to size. The results, published over many succeeding years and thus partly belonging to the era discussed in section V of this chapter, showed

- (a) It is somewhat paradoxical that all of these difficulties were occurring while the Hanford and University of Washington programs were sailing along splendidly. Perhaps one reason was that the Columbia River Project was, much of it, financed from operating rather than research funds. Obviously, the tie-in to major fisheries problems did no harm.
- (b) We will examine the others in later sections of this chapter and in chapter 12. When we contemplate the excellence of the staff and work of the present Environmental Sciences Division of ORNL and its facilities (see section V), we can feel only relief and satisfaction that the original organizers persevered.

FIGURE 11.4. Inoculating trees with radioisotopes—Oak Ridge Ecological Research (Auerbach and Schultz 1962).

that most of the cesium was cycling out of the trees into the litter on the forest floor. The litter protected the root zone from rapid re-entry into the system because there were several inches to traverse. Recycling in the trees was therefore slow. However, processes occurring in the litter and exposure of other organisms to the radioactivity in the litter could be important.

Work with mammals was accelerated by adding Paul Dunaway and later Stephen Kaye, to help him. Kaye later headed up the environmental sciences work.^(a) Among other things, changes in the blood picture of the native rodents were investigated.

Obviously, the Clinch River was the object of many investigations beginning even in the early 1950s. This system was hardly the all-consuming effort that the Columbia River system was, but it had many features in common. In 1962, the DBM of AEC produced a summary report concerning the onsite ecological research at ORNL (Auerbach and Schultz 1962). The headings for projects in the aquatic studies section are reproduced below to give the flavor of the enterprise:

Aquatic Studies. . . .

The suspended microbiota of the Clinch River and adjacent waters, in relation to radioactivity in the summer of 1956.

Uptake of cesium-137 by cells and detritus of *Euglena* and *Chlorella*.

(a) Kaye directed the Health and Safety program in the early 1980s.

The role of the fresh-water crayfish as an agent in strontium concentration.

Analysis of the bottom organisms from Clinch River mile 23 to Tennessee River mile 560.

The role of heterotrophic microorganisms in the concentration of specific radionuclides on organic matter.

Uptake and elimination of cobalt-60 by a species of crayfish, *Cambarus longulus longirostris*.

The role of tubificid worms in the transport of radioactive bottom sediments in the Clinch River.

The biogeochemistry of strontium and calcium in mollusks of the Clinch and Tennessee Rivers.

The effect of effluent atomic wastes on *Chironomus tentans* Fabricius population as determined by salivary gland chromosome analysis.

The biogeochemistry of strontium and cesium in the white crappie (*Pomoxis annularis*).

Application of radionuclide uptake and bioaccumulation data to the study of fish population dynamics.

(Auerbach and Schultz 1962)

A similar summary listing for research in terrestrial areas contaminated by radioactive wastes includes work with trees; crops; insect-bird food chains; accumulation of isotopes in grasshoppers; radiation effects on two species of sedge; surveys of mammals and other vertebrates, including pathological conditions found; and much on the movement of key radionuclides. Much of this work contributed to the designation of "critical pathways" in calculating population exposures (see chapter 15).

Specifics from the Oak Ridge ecology program of these earlier years can be gleaned from reviews prepared for the same volumes already cited for the Hanford work. At the first radioecology symposium, we find papers on radiostrontium and radiocesium in insects (Crossley 1963); bioaccumulation of radionuclides in mammals (Kaye and Dunaway 1963); an analogue computer model for the movement of nuclides through ecosystems (Olson^(a) 1963); cycling of ¹³⁴Cs in White Oak trees (Witherspoon 1963); strontium and calcium relationships in the Clinch and Tennessee Rivers (Nelson 1963); effects on the mammal populations of the White Oak Lake bed (Dunaway and Kaye 1963); changes in salivary gland chromosomes of larvae of an insect population (Nelson and Blaylock 1963); biological and environmental behavior of ruthenium and rhodium (Auerbach and Olson 1963); and various ways in which radioactive tracers were used to study movement of animals, decomposition of forest litter, food chains, etc.

The body burdens of several radionuclides in muskrats from the White Oak Lake bed are given in table 11.2, which shows that the amounts are not insignificant and that large variations are characteristically seen. One of the important needs for future work developed from these programs is to explain these variations. They are not random. They are part and parcel of the complex ecosystem.

(a) Olson was added to the ORNL ecology group to provide more mathematical and modeling capabilities.

TABLE 11.2. Body Burdens of Radionuclides for Muskrats Collected from the Oak Ridge National Laboratory Settling Basin, 1960 to 1961¹

Animal Number	Burden of Radionuclides (microcuries)

It is somewhat surprising to find in the paper by Dunaway and Kaye (1963) that pathologic effects could not be demonstrated in the various mammalian forms collected. Chromosome aberrations *did* turn up in the insect larvae collected.

The importance of having such a program in a completely different geographical area from the Hanford site should be emphasized. The terrestrial programs at Hanford and, as we shall see later, at the NTS concerned desert environments. Radionuclide transfer paths might be quite different there from the moist forests of Tennessee. Even the Clinch River studies contrast sharply with those of the Columbia. The volumes of water and effluent are relatively small in the Clinch River system; plankton plays a more important role in radionuclide uptake. The system is warmer, slower moving, and more polluted, and the species inhabiting it are quite different in toto.

The environmental effort at Oak Ridge during the period of interest here was augmented considerably by the addition of the "Health Physics Reactor." This was placed in a wooded region and provided an unshielded source of neutrons and gamma rays for many purposes. The ecology group measured effects on the flora surrounding it and found much the same differential sensitivities of plants as the Brookhaven group had found with their large gamma-ray field (see section III D). Also, the ORNL group did much work under laboratory conditions on the effects of gamma irradiation in a variety of organisms. Details can be found in the summary report cited above (Auerbach and Schultz 1962); they are beyond the scope of this discussion since they involved only external radiation sources.

C. Savannah River Ecology Program

At the beginning of the decade of the 1950s, the AEC, with the support of Congress, the Joint Committee on Atomic Energy, and the military, decided that a second major production site for plutonium was needed along with the then highly classified radionuclides concerned with the fusion process. A site of about two hundred thousand acres was chosen along the Savannah River in South Carolina. Without the urgent schedules of the MED days, there was opportunity to do some preliminary ecological work before the plant was constructed and to take advantage of some unique opportunities. Some of the area had been under cultivation prior to the acquisition of the land by the government. Its gradual reversion to the wild state, i.e., the "old field phenomenon," plus the fact that several distinct geographical situations were involved, made the site of prime interest to ecologists. Furthermore, it would be largely closed to the public, so studies could be carried out in a protected environment.

An initial ecological study was made of the Savannah River by the Academy of Natural Sciences of Philadelphia. This provided base-line measurements of plants and animals in the river before plant construction and operation began. This work has continued, particularly by using diatoms, single-celled algae, as "markers" for the health of the river.

Also in 1951, the AEC made arrangements with Eugene Odum at the University of Georgia to begin an inventory-type ecological study of the entire area and to plan ecosystems research. There was, of course, no manmade radioactivity present since the plant was yet to be built. Dr. Odum, probably the dean of American ecologists, seized on the opportunity to have a protected outdoor laboratory for both experimental studies and observation of the succession of flora and fauna. He and three graduate students began by commuting from the University of Georgia in Athens and "conducted their research out of suitcases and an abandoned barn" (SREL 1979). Soon one of the better of the dwellings that had been vacated was pressed into use as a field station ("Bush House"). The operation was called the *Savannah River Ecology Laboratory*.

It was not until 1962, almost the end of what we are regarding as the early postwar years, that a more permanent facility was built, and full-time research staff were placed onsite. Dr. F. B. Colley was the first director. The close relationship with Eugene Odum and the University of Georgia continued.

The Savannah River work was perhaps the least single-minded of those we have reviewed thus far. The reactors produced large quantities of warm, even hot water, which could be used for studies of thermal stress. There were large quantities of tritium being emitted from the stacks. The usual radionuclides were in the waste water streams in controlled small quantities. The usual problems of waste disposal existed. A large lake and several ponds, which allowed progressive analysis of the interaction of a large nuclear facility and a fairly well-characterized environment, filled out the opportunities.

Work of particular pertinence to radionuclides included monitoring of the separations processes, waste disposal and reactor operations, and development of information on food chains in each of the several distinct environments. The effort went far beyond control purposes. Over forty thousand analyses were made each year on environmental samples of air; water in streams; underground water and drinking water; milk and other farm products; vegetation; animals and waterfowl; fish, crabs, and oysters; and algae and diatoms (Bebbington 1973).

A general overview of the extent and kind of environmental sampling utilized is shown in figure 11.5. At the risk of anticipating concepts we will take up in more detail further along, the summarized findings are shown in figure 11.6A and B.(a)

FIGURE 11.5. Environmental monitoring locations around the Savannah River Plant (SRP) on the South Carolina side of the Savannah River. For scale orientation, the SRP is about 20 miles east of Augusta, Georgia. (Redrawn from Bebbington 1973.)

These figures show the large amounts of tritium and noble gases in the operation of this facility. Compared to Hanford and Oak Ridge, this site had relatively more of these radionuclides. Since the biomedical problems of tritium were reviewed extensively in chapter 10, and we will need to add further environmental aspects in chapter 12 when we consider weapons tests, we will not

(a) Although these are from a 1973 document, the nature of the emissions has not changed very much since the time the plant opened.

FIGURE 11.6A. Radio-nuclide releases and calculated doses from operations of Savannah River Plant (Redrawn from Bebbington 1973.)

FIGURE 11.6B. Radiation dose originating from Savannah River Plant for nearby resident compared to doses from other sources. (Redrawn from Bebbington 1973.)

review the subject in detail here except to point out that emissions of the more toxic radionuclides at such levels would, of course, be intolerable. It is fortunate that tritium and the noble gases are among the less toxic radionuclides.

Figure 11.6A also illustrates the impressive ability of the environment to dilute large quantities of relatively inert (chemically) substances. With releases of over a million curies per year of tritium and the noble gases, the average dose to a person at the plant boundary is only 1.5 mrem/yr.

The connection with the University of Georgia was formalized as an Institute of Radioecology, and it still continues.^(a) Most of the work involving radionuclides has borne primarily on assessment of releases, doses, etc. The more purely research aspects have concerned more classic ecology. A measure of the scope of interests and activities at the Savannah River-University of Georgia facility can be seen in the review given by Odum at the first Atoms for Peace Conference (Odum 1956). He emphasized the need to study whole communities of organisms and illustrated the types of work by such classic ecological methods as productivity of the organisms in a coral reef by measuring oxygen flow, the annual community turnover of biomass, measurements of trophic

(a) At the cutoff time for this chapter; see preface.

structure (i.e., the overall food chain) measurements of species structure, and the comparison of contaminated and noncontaminated areas. This was indeed classic ecology with one new variable introduced—radioactivity.

As a final commentary on the activities at these three major sites in the MED and early postwar years, we can look at table 11.3, taken from a paper by authors from all three laboratories and given at the second Atoms for Peace Conference (Brown et al. 1959). The figures concern experience with disposal of radioactive wastes.

TABLE 11.3. Comparison of Three Major Production Sites (liquid radioactive wastes)

	Cumulative Total Volume (liters)	Cumulative Total Gross β -Emitter Activity (curies)
Savannah River	5.0×10^8	$2.4 \times 10^{2*}$
Oak Ridge	2.6×10^7	1.0×10^5
Hanford	1.2×10^{10}	2.4×10^6

*Not including 2300 curies of ^{131}I .

Source: Reset from Brown et al. 1959, p. 556. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1959.

The cumulative figures are, of course, not strictly comparable because the sites had not been in operation for equal periods. They show, however, that the average activity^(a) is lowest at Savannah River, highest at Oak Ridge. They also emphasize the fact that waste disposal is and will be a much greater problem than day-by-day releases. The conclusions of this paper are premonitory of the enormous effort that was to be needed and is still needed on waste disposal problems. They are quoted below.

The problems associated with the disposal of high-level radioactive wastes are certainly large and serious. However, the problems associated with the low to intermediate level streams, bulking many times the volume of Savannah River high-level waste, are also of great importance. Even the essentially uncontaminated process cooling water cannot be released into many public waterways owing to its potentially significant radioisotope content. The experiences at Oak Ridge, Savannah River and Hanford point out means by which disposal may be accomplished but not without the assumption of an extensive and exhaustive research program and the grave responsibilities associated with that disposal. (Brown et al. 1959)

The net result of the MED and early postwar work at these three major sites was that releases of radioactive materials had been normally below the limits for detection of effects on man or the biosphere, but the enormous legacy of radioactivity awaiting safe disposal would require the best efforts of the future.

(a) In terms of concentration.

D. Other U.S. Activities in the Early Postwar Years

There were, of course, monitoring programs and some ecological studies around facilities other than the three major production sites discussed above. These include uranium ore processing and refining mills, the major AEC laboratory sites, and also many research projects mounted by universities with interests in ecological research. Although much of the activity concerns weapons fallout and will be detailed in chapter 12, we need to consider here those activities that were qualitatively like the larger ones already taken up.

1. Uranium Mills and Refineries

There were several uranium processing mills (concentration plants) located primarily in the West, not too far distant from the mines. These processed the uranium ore for removal of other radionuclides such as ^{226}Ra and the members of its decay series. In addition, there were many refineries located primarily in the East and Midwest. Many of these were dusty operations, and much attention was paid particularly through help from and direct measurements by the Health and Safety Laboratory (HASL) of the New York Operations Office of AEC to proper measurement and evaluation of airborne uranium dust and the exposure of workers and the immediately surrounding population. These operations have been alluded to in chapters 8 and 9.^(a) A succinct history of the uranium production chain and early occupational exposure experience is provided by Eisenbud (1975), also in the recent book by Whicker and Schultz (1982).

The principal environmental problems arose around the mill sites. These mills put aside the residues from the processes of concentrating uranium as "mill tailings." Millions of tons of such tailings had accumulated by the late 1950s. They contained several thousand curies of ^{226}Ra . Even though the tailings impoundments were partially stabilized and partially contained, it was only a matter of time before elevated radium concentrations began to appear in streams and in water supplies derived therefrom for drinking and irrigation. The first data appear to have been generated prior to some Congressional hearings in 1959. The most highly publicized, early case of radium contamination involved the Animas River in Colorado-New Mexico. This river provides drinking and irrigation water for Aztec and Farmington, New Mexico. The ^{226}Ra content of the river and drinking water was measured by USPHS officers and staff, primarily under the direction of E. C. Tsivoglou, whom we met in chapter 3 in connection with radon problems (Tsivoglou 1959; Tsivoglou et al. 1960), with a follow-up in the first Radioecology Symposium showing effects on biological fauna in the river (Anderson, Tsivoglou, and Shearer 1963).^(b)

The radium concentrations in the Animas River below Durango, Colorado, where the mill was located were markedly higher than above the mill. Indeed, consumers of untreated water would have received, had they used it, about 300% of the maximum permissible daily intake of radium on the basis of standards of the International Commission on Radiological Protection (ICRP) (chapter 16). The drinking water in Aztec and Farmington was at 170% and 140% of the

(a) The details appear in part in the two symposia on occupational health experience with uranium, viz., Energy Research and Development Administration (ERDA 1975) and HASL (1958).

(b) Tsivoglou was then working out of the Taft Sanitary Engineering Center of the USPHS in Cincinnati, while Anderson was at the PHS office in Dallas.

permissible daily intake, respectively (Eisenbud, 1973). All of these concentrations of radium were, when first measured, several hundred times the normal for these waters. It appeared that radium was entering from untreated liquid wastes at the mill and through run-off from the tailings during rainy periods. Unlike the situation described in chapter 3 for the uranium mines, the mills were an AEC responsibility, and steps were soon taken to correct the run-offs. By 1963, the radium content of the river was only about three times as high below as above the mill rather than several hundred times. However, as water standards for radium have gone downward (see chapter 16), the acceptability of the measures taken or even possible has gone down correspondingly. The problem is still with us.

In addition to water leakage from the tailings, additional problems were brewed by the release of radon gas and the transfer of dust by wind. Measurements were aided again by the New York Health and Safety Laboratory. As a result, the tailings sites have been covered with topsoil and plantings. The current situation is a great improvement, since the present radon values are well below the accepted limits for the public. Indeed, Whicker and Schultz (1982) consider the current hazard from these sites as small and easily managed.

A succinct and readable summary of how the mill tailings problem grew and affected one community, Grand Junction, Colorado, is given by Siek and Baird (1972) from the Colorado Department of Health. This discusses air and water pollution studies and then elaborates on the fact that mill tailings had been removed from the mill site and used for construction of houses, surfacing of roads, etc. There was a significant radon problem generated thereby. It also reviews the resulting indoor radon studies, the enactment of legislation regarding containment of uranium mill tailings, and the development of levels at which remedial action should be instituted.

Clearly, there is a population that in the years of our interest in this section received doses considerably larger than those at the major production sites, except for accidental releases. Unfortunately, the population is too small to support a viable epidemiologic study for determining effects of either the waterborne radium or other chemicals, or the radon in air. The only indication of biological effects came from the studies of Anderson, Tsivoglou, and Shearer (1963) and Tsivoglou et al. (1958) on the river organisms. There is no question that the bottom fauna in the Animas River from below the mill to at least the New Mexico state line were greatly reduced in number and that the food supply for fish in that stretch of the river was also reduced. Concentration factors (see preface and section VI) for radium in the biota ranged from one hundred to one thousand. Unfortunately, the mill effluents contain many chemically toxic substances as well as the radionuclides. Thus, the change in abundance of bottom fauna cannot be ascribed to any single factor. We can only speculate on the role of radium.

The refineries were not, in general, of much ecological importance during the years we are considering here. They were more contained operations and did not have a phenomenon like the tailings piles around the mills. Only in very recent years have they become of concern to environmentalists and stimulated research, as we will see in section V. By and large, the refineries were spared the problems of disposal of radium because they received a purified starting material for their operations.

When the process gets as far as fuel fabrication, environmental concerns become truly minimal. Only in the event of serious accidents (both uranium

and plutonium metal are pyrophoric), usually explosive reactions, does environmental contamination become of concern.^(a) The intrinsic value alone of the materials by this stage ensures strict containment in routine operations.

2. Reactors

We will postpone discussion of nuclear reactors in the United States to be able to consider the problems of modern reactors as a unit. Because of its landmark character, we will review the Windscale reactor incident in the United Kingdom in some detail in section III E.

3. Fuel Reprocessing Plants

As we have seen, the Hanford and Oak Ridge sites had facilities for fuel reprocessing. The Savannah River complex was added in the period we are calling the early postwar period. It had a large fuel processing capability. A plant at the Idaho Falls Nuclear Reactor Testing Station came soon thereafter. Also, there were privately owned reprocessing plants, but these came along in a later period.

The chief concern regarding environmental contamination around these facilities comes from the relatively enormous amounts of radioactivity that must be handled. Nevertheless, only the facilities integrated into the large production sites have been part of an integrated environmental and ecology program. The rest have had ample surveillance activities, but not work that would qualify as research for this volume. Eisenbud (1973) gives a clear review of some of the activities of and around fuel reprocessing plants, with special emphasis on a plant built under the aegis of New York State at West Valley, New York. This went into service in 1966, but there were many problems, financial and operational. With the decline of nuclear power activities, the facility is on a standby status.

4. Other U.S. Government Laboratories

Each of the major national laboratories had from some to considerable interest in environmental and ecological problems.

We have already reviewed the considerable interest at Argonne National Laboratory (ANL) in radium in natural waters (chapter 1). Later they became interested in actinide elements in the Great Lakes and in fallout problems. Also, the group mounted many laboratory investigations with ecological significance.

Brookhaven National Laboratory (BNL) has been a center for ecological research and work bearing on the environment almost since its founding. Its involvement with radioisotopes bears primarily on the fallout events in the Pacific and will be described in chapter 12. Its other major activity centered on the gamma field. This was a multicurie source of gamma photons placed in a large field with woods nearby. Much of our information on the relative radiosensitivity of plants, from primitive to complex, in a natural environment came out of the work of Sparrow and his colleagues at Brookhaven using this facility. In addition, the group has carried forth much basic laboratory research on lower organisms. We have met much of this in connection with specific radio-nuclides (e.g., tritium).

(a) Eisenbud (1973) describes a significant release of plutonium by explosion in a chemical processing plant at Oak Ridge in 1959. There have been other isolated releases, but these have been small compared to the operations.

We have already had many occasions to encounter the work of the AEC Health and Safety Laboratory. This laboratory supplied instrumentation and special services to the weapons testing operations, developed the worldwide network for gathering and measuring fallout, and studied fallout radionuclides in food and water, etc. Indeed, there were few aspects of environmental contamination with radioisotopes that HASL was not involved with. The staff was even able to mount research in its own right.

The Knolls Atomic Power Laboratory, the back-up for the Naval Reactor program, is reported by Kornberg and Davis (1966) to have done a small amount of environmental work on its releases of radioactive materials.

The Los Alamos Scientific Laboratory (LASL) has had programs to assess the movement of radionuclides, especially plutonium, in the canyons on the site used for waste disposal. However, its principal involvement with environmental concerns centered on the NTS and selected aspects of the work at the Pacific Proving Ground that involved the physicists at Los Alamos. In addition, there was laboratory work on lower organisms with applications to ecological problems.

The Puerto Rico Nuclear Center has a reactor and other facilities and cooperates with the University of Puerto Rico in a radioecological study of a rain forest (external radiation source). The group at Mayagüez has become considerably involved with marine ecology and the movement of radioisotopes in marine environments. Their work has not been site-oriented to a significant degree and appears in later chapters.

The U.S. Bureau of Commercial Fisheries at Beaufort, North Carolina, particularly T. R. Rice and his colleagues, has had both research and surveillance activities regarding contamination of the marine environment. This group has worked closely with other aquatic biology groups, particularly the one at Savannah River.

The Woods Hole Oceanographic Institution, not strictly a U.S. government installation, but subsisting almost entirely on governmental contracts, has been very active in research on radioisotopes in the marine environment. The work has been spearheaded by Vaughan T. Bowen.

An informative overview of the environmental surveillance activities at all AEC sites can be obtained from a series of annual reports entitled "Environmental Monitoring at Major U.S. Atomic Energy Commission Contractor Sites." A typical example is the one issued for the calendar year 1973 (AEC 1973a). Activities at twenty-eight sites are described in a more or less uniform format arranged in order of the operations offices. Some glimpses are given of new ideas, such as the use of the honeybee as a monitor for tritium at Los Alamos. (It was more reliable than the air monitors!) Each one has a section on dose to the public. Anyone wanting to see what measures were taken at the sites to protect the public and the environment can learn much detail (but not so much philosophy) from these documents.

The other major governmental participant (if we consider the Naval Reactor program as part of AEC) was the U.S. Public Health Service.

We have already seen that the PHS eventually took an active part in evaluation of uranium miners (chapter 3) and acted promptly in uranium mills (section III D, above). In addition to the team they sent to Hanford soon after the war, the PHS has also assisted with surveys on the Savannah River estuary and on the Clinch and Mohawk Rivers (Sobo and Bedrosian 1963). The largest involvement of the PHS has been through its regional laboratories and officer

assignments. Some of the early ones were temporary satellites of the Robert A. Taft Engineering Center in Cincinnati, e.g., the Environmental Health Center at Oak Ridge where Melvin Carter was assigned in 1951-1953 (Carter 1979). There were short-term assignments of PHS officers to the early weapons test organizations, such as Crossroads and the Nevada Tests. Later the assignments came from the regional centers.

The regional centers of the PHS all conducted research bearing on environmental concerns. Indeed, we have seen some of the research, especially on noble gases and related areas in previous chapters. None was any more intimately involved with ecological and environmental problems than the Southwestern Regional Laboratory in Las Vegas, Nevada. This group was involved with the Pacific tests, as were other PHS personnel, and was very active, especially in the offsite monitoring, at the NTS. The three regional laboratories (Southwestern; Las Vegas; Northeastern, Winchester, Massachusetts; and Southeastern, Montgomery, Alabama) plus the Robert A. Taft Center and an occasional recruit from the National Institutes of Health (e.g., H. L. Andrews and F. Smith; see chapter 12) resulted in a diffuse, but considerable involvement of the U.S. PHS in most aspects of the environmental and ecological problems around the many production sites^(a) and in the weapons testing activities. As we have seen, this included several independent teams that sort of "double-checked" the findings of the large contractors. This author can find no reports that they differed in any substantive ways. Yet, the skeptical should have taken some comfort in having an independent agency of the U.S. government totally dedicated to health problems and with no possible conflict of interest in meeting test schedules or getting weapons data make confirmatory surveys and report comparable results. We will save the rest for chapter 12.

5. The Universities

Nearly every major university in the United States became involved directly or indirectly with environmental problems of radioactivity through work connected with fallout. The same was true, but to a lesser degree, in other parts of the world. A few U.S. institutions, especially ones with large AEC contracts, devoted major efforts to broad aspects of radioecology.

We have already mentioned the deep involvement and excellent work of the fisheries laboratory at the University of Washington and the close ties between the Savannah River Plant and the University of Georgia (sections II A and C).

The University of California system had active surveillance programs around all of its large installations. However, of greatest interest to our purposes are the research enterprises developed. Outstanding among these are the Scripps Institution of Oceanography, part of the University of California at San Diego, and the University of California at Los Angeles (UCLA). As a major center for oceanography, it was natural that the Scripps Institution would become deeply involved in the behavior of radioisotopes in the marine environment and in possible biological effects as a result of the problems of fallout and of waste

(a) A handy manual on routine surveillance of radioactivity around nuclear facilities was issued in 1966 under the aegis of the Division of Radiological Health (PHS 1966). This covers surveillance of air, food, water, biota, soils, precipitation, and in-vivo measurements of people.

disposal. The Scripps group participated very actively in the fallout surveys in the Pacific and mounted experimental work both in the field and in the laboratory. Scripps personnel played key roles in the development of National Academy of Sciences-National Research Council (NAS-NRC) reports on the effects of atomic radiation on oceanography and fisheries already cited.

The involvement of UCLA was primarily through its Atomic Energy Project. Stafford Warren, who went to UCLA at the end of the war as dean of the new Medical School, kept his interests in atomic energy and in environmental contamination problems alive through the project. Indeed, a major portion of its resources and personnel were directed to and still are at the NTS, and they were deeply involved in all biomedical aspects of the Pacific tests. Naturally, a considerable amount of laboratory research was mounted to check out various ideas arising from the findings in the field (chapter 13).

Some work on terrestrial radioecology was carried out on the Davis campus of the University of California. Most of that effort, however, was in the long-term laboratory animal studies discussed in chapter 8.^(a)

Colorado State University at Fort Collins has long had a unique capability in radiobiology extending from a large beagle dog experiment involving external radiation through cellular and molecular radiobiology to broad interests in radioecology. Through use of special sites in the Colorado Rockies as well as experiments on the campus, they have been involved with many studies, from local events to worldwide contamination from fallout. Their work has not been site-specific to Fort Collins. Ward Whicker, whose book with Vincent Schultz we have already mentioned several times, has his headquarters at Colorado State. Note also that this was the institution that hosted the first formal symposium in radioecology (section IV).^(b)

Emory University in Atlanta, Georgia, developed a strong radioecology program built around a reactor operated by Lockheed Aircraft Corporation for studies of shielding. This was a mixed neutron and gamma radiation field. The Emory group did not enter the arena of radioisotopes in the environment.

The University of Michigan, Michigan State, and the University of Minnesota have had interests in radioecology, but we will not be able to pinpoint their work beyond sponsorship of symposia, etc. (section IV).

Finally, in this brief listing of universities involved with radioecology in the decade or so after World War II, we should mention New York University, even though we have already seen their work in other fields. Through its Institute of Environmental Medicine (originally Occupational and Environmental Medicine) with facilities at Sterling Forest about fifty miles north of New York City, New York University has kept many programs active that bear on radioecology. Some of these represent a carry-over of the interests of Merrill Eisenbud from his experiences as director of the New York Operations Office of AEC. They include studies of high radiation background areas of terrestrial origin in Brazil

(a) The Lawrence Livermore Laboratory of the University of California had much of its biomedical program built around environmental contamination problems. This developed, however, in the years beyond those under discussion in this section.

(b) The University of Colorado at Boulder was involved in many aspects of fallout work through its Institute of Arctic and Alpine Research.

and India,^(a) ecological studies of the Hudson River estuary, with special emphasis on the Indian Point reactor, and much work on radium and the actinides in natural and manmade settings. They had considerable involvement with the characterization and measurement of fallout. Their work in pulmonary toxicology has already been reviewed (chapter 9). Later they expanded into the area of marine systems. The work most cogent to this chapter, however, is that concerning the Hudson River estuary. We will examine it briefly in a subsequent section.

Many other university organizations have been involved with radioecology to some degree. The listing above makes no claim to being complete. However, it does enumerate those groups we will have most occasion to cite directly or indirectly in subsequent pages of this chapter and later chapters.

E. Work Abroad

The field of radioecology was primarily a U.S. concern during the early work at Hanford and Oak Ridge. With development of reactors very early postwar in the United Kingdom and the USSR, interest in environmental contamination developed quickly. Russian work went early to problems of the aquatic environment. Indeed, enough work had been done in the USSR to provide about sixteen pages of Russian titles in the fifties and early sixties in a very useful book by Polikarpov (1966). This book is also an excellent review of work in other countries, especially the United Kingdom and United States (approximately eighteen pages of references to the non-Russian literature), but including Canada, Finland, France, Germany, Italy, Japan, Monaco, and Sweden as well.

The work abroad, like that in the United States, involves both external radiation sources and radionuclides, especially, of course, those in fallout. There is not so much of it specific to production sites, the subject of this chapter, in the early postwar years except in the U.K. work. The Polikarpov book is about equally devoted to data resulting from generic site measurements (but not specific sites), fallout measurements, and controlled laboratory investigations. Other references to Soviet work can be found in the bibliography to chapter 1 of the book by Whicker and Schultz (1982).

1. Canada

Site-specific research and surveillance has been carried along regularly by the Canadian Atomic Energy Authority. The most research oriented has been around the Chalk River installation of Atomic Energy of Canada, Ltd. The earlier literature is, however, rather sparse, at least in sources available to this author.

An early report was part of a summer symposium on the role of atomic energy in agricultural research held at Oak Ridge in August 1952 (Comar and Hood 1953).^(b) It was summarized in the Newsletter of the Oak Ridge Institute

(a) The essence of the work in Brazil has now come to fruition. At the 1985 annual meeting of the National Council on Radiation Protection and Measurements (NCRP), Eisenbud delivered an eloquent summary that raised questions about the need for some aspects of the billion-dollar effort now going into high-level radioactive waste disposal. Despite a potentially large source of radioactivity (thorium series isotopes) contained in a mountain, essentially none was found in surface or ground water. In Eisenbud's review, he states that the materials are extremely firmly fixed chemically and will remain so for eons.

(b) The Canadian work is outlined on page 482.

for Nuclear Studies, September 1952. R. R. Langford and F. H. Rigler discussed organisms and bottom deposits in the Ottawa River above and below the Chalk River plant. They showed wide variety in the rate and total accumulation of radionuclides. The accumulation increased in the approximate order: rooted plants, epiphytic plants, bottom insects (burrowing less than surface bottom insects), small clams, minnows, and small fish. There was seasonal variation in the accumulation as a function of water temperature—based, of course, upon fluctuations in metabolic rate of the organisms.

At the first radioecology symposium, Ophel (1963) presented a detailed discussion of the fate of radiostrontium in Perch Lake, Ontario, which is situated within the Chalk River establishment.^(a) A scan of the results can be gained from figure 11.7.

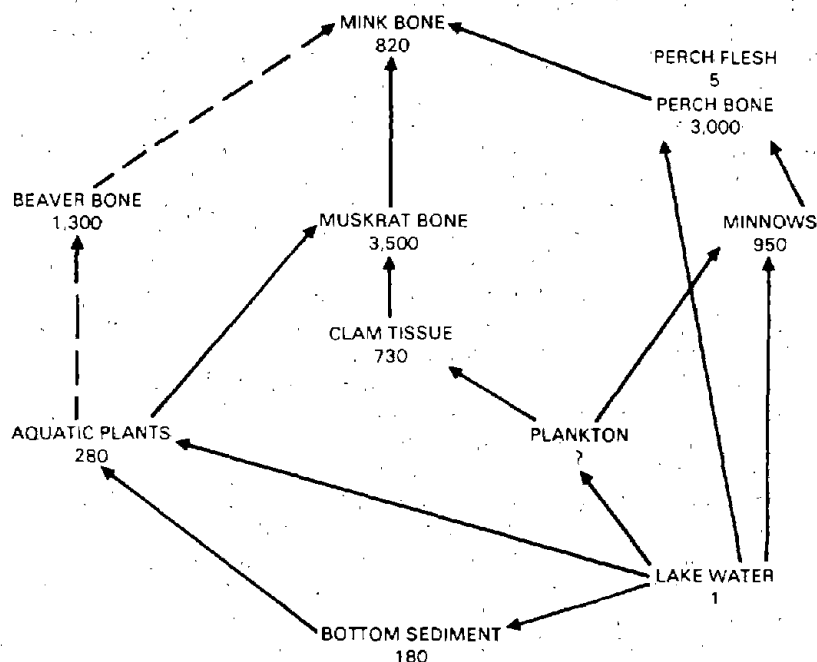

FIGURE 11.7. Average concentration factors* for ^{90}Sr in Perch Lake food web. (Redrawn from Ophel 1963. Reprinted with permission of Van Nostrand Reinhold Co., Inc., copyright 1963.)

$$* = \frac{\text{Concentration in Aquatic Organisms}}{\text{Concentration in Aqueous Medium}}$$

Obviously, the concentration factor for strontium is much greater for bone than for flesh as would be expected, but there are significant differences between species. (Fortunately, we do not eat the bones of any of these species.) But note that aquatic plants can be higher than perch flesh and that there is a considerable amount deposited in bottom sediment.

(a) This lake received dissolved radionuclides from adjacent liquid waste disposal areas beginning in late 1955.

A large effort took place at Chalk River in connection with their contamination accident. However, that was primarily within the building and is not pertinent to the present discussion.

2. The United Kingdom

The first British production reactors went into operation in a remarkably short time after the end of World War II, i.e., 1950–1951. (Licensing was not the hassle then that it is now!) The location was Windscale on the Irish Sea in north-western England. There were two air-cooled graphite-moderated natural uranium reactors used for the production of plutonium and an associated chemical processing facility. Waste from this fuel processing facility has been discharged into the Irish Sea for many years. First there was an experimental discharge of about 10,000 Ci of radioactive effluents over a period of about six months in 1952 (Eisenbud 1973). When it was found that the activity of the water was from 0.01 to 0.1 $\mu\text{Ci/ml}$, it was deemed safe to continue the practice, even increase the annual releases. The principal radionuclide discharged was ^{106}Ru .

The U.K. Atomic Energy Authority kept very close tabs on the contamination of the sand, the silt, the seaweed, and the fish, and by the time of the second Atoms for Peace Conference in Geneva they were ready to make international disclosure of their findings (Dunster 1958). They had studied the dietary habits of local residents and determined that one species of fish and a seaweed used in preparation of a local bread (laverbread) were the critical pathways for human exposure. They designed some limits, found that, of the nuclides being discharged, ^{106}Ru was the limiting one in the seaweed and determined that a discharge rate of 7,000 Ci per month would be acceptable.^(a) Eisenbud (1973) points out that, if the laverbread pathway had not existed, fish would have been the critical pathway, and the permissible releases could have been much higher. In typical British fashion, there was no thought at all of trying to change the dietary habits that had existed in the population for generations. Public relations around the plant were tenuous enough without that.

These discharge rates for "low-level" radioactive waste seem high, especially when compared to those for total radioactive waste from three U.S. sites shown in table 11.3. We must remember, however, that these figures are very site-specific. Eisenbud (1973) gives a tabular survey of the isotopic composition of Windscale wastes derived from work of Howells (1966). The Dunster paper already cited expands into use of the Windscale information for "safe discharges" into other coastal waters.

There was, of course, a terrestrial survey and technological assessment. The graphite reactor puts out radioactive noble gases, radioiodine, and other fission products in very small quantities with the cooling air. The terrestrial survey data were discussed publicly by the British even before the aqueous discharge data quoted above. Fair and McLean (1956) describe use of mobile laboratories to do alpha, beta, and gamma surveys of an area with a radius of about twenty miles of the Windscale Works before the plant was constructed. As with many background surveys, the local variations were large. No single figure could be assigned to any one point. However, the influence of many meteorological conditions was pinpointed.

(a) Total beta activity could have been 20,000 Ci per month, while any sizeable amounts of ^{90}Sr or plutonium isotopes would have reduced the limit drastically. Work on the Irish Sea is still going on.

The same routines were conducted after the plant went into operation. The results were comparable to the old air-cooled graphite reactors at Brookhaven and Oak Ridge in the United States. Chamberlain et al. (1956) from the Atomic Energy Research Establishment at Harwell published a careful analysis of tolerable levels of ^{131}I , ^{90}Sr , and ^{89}Sr in food chains. This analysis included the scenario of daily depositions, intermittent deposition, or total deposition of fission products in soil in which crops were to be grown and allowable amounts in herbage versus milk. An interesting conclusion was that hazard from ^{131}I from herbage would lead to permissible discharges a factor of one thousand lower than the hazard from breathing radioiodine (see chapter 10). Permissible amounts of ^{131}I and ^{89}Sr were comparable in this system.

This routine surveillance at Windscale became far from routine in October 1957. Release of stored neutron energy in the graphite core of Reactor Number One was excessive in certain areas, but went undetected because of insufficient instrumentation to cover all parts of the core. Metallic uranium and graphite began to react with air and many fuel elements burned over a period of four days. The incident is described graphically by Eisenbud (1973, pp. 411-412); by Dunster, Howells, and Templeton (1958);^(a) and by Denham and Waite (1982). The isotopes released to the environment were ^{131}I , 20,000 Ci; ^{137}Cs , 600 Ci; ^{89}Sr , 80 Ci; and ^{90}Sr , 9 Ci.^(b) Presumably the preponderance of iodine was due to its greater volatility.

The survey activities included estimates of the external radiation hazard, inhalation hazards, and hazards from ingestion of contaminated food and water. It was soon clear that the first two were negligible compared to the third. A milk sampling network was quickly established. By recruiting personnel and equipment from places like Harwell, Aldermaston, Woolwick, etc., and devising a quick method of measurement, they were able to analyze several hundred milk samples per day. The highest activity reading was $1.4 \mu\text{Ci}/\text{mL}$ obtained from a farm about ten miles downwind from the reactor and about four hundred feet higher. The activity/time relationships for the iodine in milk are shown in figure 11.8, taken from the paper by Dunster, Howells, and Templeton.

It was soon realized that use of milk from some local farms would have to be stopped. Very quickly, a level for restriction was decided upon, viz., a level in milk such that normal intake would result in a dose of no more than 20 rad to the thyroid.^(c) The milkshed survey covered about two-hundred square miles, which are mapped by Dunster, Howells, and Templeton (1958). Milk deliveries were controlled or stopped throughout this area.

(a) The review by Dunster and colleagues was at the second Atoms for Peace Conference held in 1958. It was the longest published paper in the proceedings, and it tells the complete story of not only the accident itself, but the countermeasures taken, measures made, and the way in which the entire British nuclear establishment acted almost as a single agency and as if they had been practicing for years for such an incident.

(b) Howells (1969) cites the release also of 21,000 Ci of ^{132}Te , an isotope that would behave much like iodine.

(c) This was derived from the knowledge that 200-rad had sometimes produced thyroid cancer in children. Since children would be the most vulnerable individuals, a level of one-tenth this amount was chosen as the cutoff point. This came out to be $0.15 \mu\text{Ci } ^{131}\text{I}/\text{L}$ of milk. The decision was checked and assented to by the Ministry of Agriculture, Fisheries and Food, which has responsibilities in the United Kingdom akin to the original responsibilities of the Public Health Service in the United States.

FIGURE 11.8. Decay curve of I^{131} in milk near the Windscale Works of the United Kingdom. Note the disappearance is more rapid than simple radioactive decay would predict. (Redrawn from Dunster, Howells, and Templeton 1958. Reprinted with permission of Pergamon Press, Ltd., copyright 1958.)

Air and ground fallout samples were measured at much greater distances from the plant, even in Northern Ireland, the Isle of Man, and into southern England. There was a well-defined plume, since the wind was relatively constant in direction, except for one or two hiatuses.

Iodine-131 concentrations were measured in drinking water, in human thyroids, in and on vegetation, and in soil. As soon as analytical facilities and personnel permitted, concentrations of the strontium isotopes were also measured in detail to be sure that the initial preponderance of iodine had continued. None of the levels of contamination found were high enough to cause undue concern at the time, although the highest dose to a child's thyroid was 16 rad and the highest to an adult was 9.5 rad.

Only the milk supply was considered contaminated enough to require interdiction. Areas were released to normal usage as the concentrations of iodine in milk declined. Some areas were released relatively soon. The last area to be released was a coastal region extending about twelve miles southward in the direction of the main plume. Even this was released before the end of November. (Note that enough strontium analyses had been done to assure that when the iodine was down the milk was safe insofar as other radionuclides were concerned.)

They even went beyond pure surveillance into research, which concerned the correlations between gamma radiation levels and iodine concentration in milk, between iodine in grass and in milk, and between strontium in grass and in milk.

The variability of sampling and measurements on ground and of grass was sufficient to make it clear that nothing could substitute for the measurement of milk itself. This was true also for other foodstuffs.

An interesting sidelight on the Windscale incident is that local unskilled inhabitants were drawn in very early to help gather samples and even do surveys of ground activity. Even though the incident was hardly welcomed by the inhabitants of the area, they seemed very willing to lend a hand in determining whether or not a health hazard existed. This was not very long after the end of World War II, and the British seemed still to have the spirit of helping each other that had brought them through the war.

There is no question that the details of the handling of the Windscale episode provided a primer for all other emergency management plans for radionuclide contamination of the environment from nuclear facilities. Even though many things would have been done differently with experience, the rapidity of the response, the quick decisions on allowable levels, not only for iodine but for strontium and other radionuclides, and the competence of all the scientists who took part from near and far rate kudos.^(a) Also, this incident underlined the need for extensive advance planning and laid the groundwork for much of the new work around reactor sites and planned reactor sites on both sides of the Atlantic.

The Fisheries Radiobiological Laboratory of the U.K. Ministry of Agriculture, Fisheries and Food, located at Lowestoft, Suffolk, which took an active part in the Windscale incident, appears to have monitored the aquatic environment of all major nuclear energy facilities in the United Kingdom on a regular basis. Mitchell (1969) gives a useful summary of their approaches and practices and assesses the radiation doses received by various critical groups in the population.

Much more could be said about U.K. practices and research in the field of environmental contamination. However, these relatively early studies should establish that the United Kingdom gained experience rapidly, even if not necessarily by design.

The Windscale incident would not go away even after the extensive reports cited above. In 1982 and 1983, there were two reports for the National Radiological Protection Board that added new information (Crick and Linsley 1982, 1983). The first report reviewed all of the data released and concluded that the total population dose ("collective effective dose equivalent," a relative of the effective dose equivalent, but integrated to infinity) was 1.2×10^3 man-sieverts and that most of the collective dose came from the ingestion of contaminated milk. It was also concluded that the banning of milk consumption in the Windscale area "saved" approximately 3.5×10^3 man-sieverts of potential exposure. These doses were calculated to be comparable to one or two weeks of exposure to natural background radiation.

The story changes some in the second report. By adding in the contribution from previously unpublished data on other radionuclides, particularly ^{210}Po , and isotopes of plutonium, the collective effective dose equivalent was increased to 2.0×10^3 man-sieverts. This was considered to be within the range of uncertainty of the earlier estimate and still not of obvious health significance on the average. However, the fact that new information could appear so long after the incident attests to the complexity of the gathering and handling of data for environmental contaminants.

(a) Probably much was gained by the directness of the operation and publication in all media of the results. The scientific publications are summarized by Howells (1969).

Further and generalized detail is seen in the inquiry stimulated by the application of British Nuclear Fuels Limited to develop a reprocessing plant for irradiated oxide fuels and various support services (Parker 1978).

3. Others

Most of the work from Europe and Asia during the period of our concern in this section is not site-specific. The large literature from the USSR concerns general problems of aquatic radioecology, worker and population exposure standards, or, later, fallout measurements, and it is more appropriate to other sections of this and later chapters. Finland, Sweden, and other north European countries published work on terrestrial and marine contamination problems. The work can be seen in the various symposia that we will cite in section IV. Investigations in Japan have tended toward fairly general discussions and measurements during the period of our interest here and are not site-specific except for in-house documents concerning their developing facilities. Again, much of it applies to fallout problems and measurements.

A site-specific discussion of concentrations of elements in fish and aquatic plants in three rivers in West Germany was presented by Feldt (1971).^(a) The three rivers were the Ems, the Weser, and the Elbe, each of which had or was about to get power reactors of the boiling-water type. The investigation centered on the interesting question of how to limit effluents in each river so that maximum permissible concentrations or above would not occur in the North Sea into which they discharged. The choice of biological indicators and probable critical pathways led to the following conclusions on the measurements and their order or priority:

1. measurement of water by direct gamma spectroscopy
2. measurement of bottom activity
3. measurement of fish and plants to determine effects if any
4. measurement of radioactivity in mussels of the estuary

The priority was based on the fact that steps 1 through 3 could be carried out on the spot, more or less.

While many other reports have addressed this general problem of the additivity of radioactivity from several sites, this one is an especially readable and clear delineation of the thinking that can be applied.

IV. Radioecology Comes of Age

The decades of the 1960s and 1970s saw the field of environmental aspects of nuclear energy grow from specialized research around three major production sites in the United States to a fully accepted specialty in the atomic energy field and in ecology. The term radioecology or radiation ecology came into use independently and simultaneously in the United States and the Soviet Union (Whicker and Schultz 1982, Vol. I). Since much of the work on such subjects, as the transport of radionuclides, concentration factors, and the like were somewhat foreign to classical ecology, there were some individuals who objected to

(a) While dated later than the nominal period we are reviewing here, the work was done over many years and thus extends back into the 1960s.

the terminology. However, it soon became established and used. A descriptive outline of the field was given in the preface to these chapters.^(a)

In 1955, the NAS-NRC Committee on the Effects of Atomic Radiation on Oceanography and Fisheries issued a landmark report (NAS-NRC 1957) with the title the same as the name of the committee. This sounded an authoritative warning regarding the dumping of radioisotopes into the marine environment and set forth the gaps in our knowledge and the researches needed. When the Academy later prepared its series of reports called *Biological Effects of Atomic Radiation*, there was a further exposition on oceanography and fisheries plus one on disposal of radioactive wastes, on agriculture and food, and on meteorology. These were issued in 1960 (NAS-NRC 1960).^(b) Other NAS-NRC reports on these problems are listed later in this section.

Also in 1960, the symposium already mentioned on radioisotopes in the biosphere (Caldecott and Snyder 1960) was held at the University of Minnesota. This drew much discussion of radioisotopes in soils and plants, effects on genetic and somatic processes, toxicity of radionuclides, etc. It included a section called "Radioisotopes and Environmental Circumstances" in which the papers by Bustad and by Kornberg cited in the previous section were presented. The subject matter in toto for these endeavors was much broader than that encompassed by the definition of radioecology given earlier. Could radioecology by itself command enough interest and be coherent enough to support a major symposium entitled "Radioecology"? As we have seen, through references already made, the people at Colorado State University Institute of Environmental Biology in Fort Collins decided to organize a national symposium and see. The symposium was scheduled for September 1961. There was an overwhelming response. Almost ninety papers were accepted for the program, plus a panel discussion on education and research training needs in the field. Over one hundred participants materialized. There was much concern among the organizers as to whether or not so large a meeting would be successful. Would the papers have enough in common to keep interest up for the necessary five days? Would they be of high enough quality? The symposium was an immense success. The papers were of high caliber and the enthusiasm of the participants for their fledgling field universal. The volume was edited by Schultz and Klément (1963). Since it is a classic marking the real birth of radioecology as a broad discipline in the United States, the table of contents is shown as note 1 at the end of this chapter.

A second national symposium was held at Ann Arbor, Michigan, in May 1967 (Nelson and Evans 1969). This had sponsorship of the Ecological Society of America as well as the AEC and the University of Michigan. This one also drew ninety papers and included a presentation by John Wolfe, director of the environment section of AEC on retrospection and future. A few of the speakers came from countries other than the United States, but not many. The symposium included, in addition to a plenary session, sessions on population and community responses to radiation; individual and species responses; radionuclide cycling in freshwater organisms and environments, in marine organisms

(a) The maturation of the field was aided considerably by the several IAEA symposia cited on p. 816, as well as IAEA 1967, 1974.

(b) A later National Academy of Sciences-National Research Council Report confirmed and extended the ideas put forth in 1957 and 1960. The introduction by Allyn Seymour is particularly recommended (Seymour 1971).

and environments, and in terrestrial organisms and environments. It was, if anything, even more cohesive than the first symposium.

In 1971, a third national symposium called "Radionuclides in Ecosystems" was held at Oak Ridge (Nelson 1971). This one required two volumes for its publication. In addition to titles similar to those listed for the second symposium, there were sessions on thermal effects, modeling, and effects on plants and plant communities.^(a) There were even some discussions of transuranic problems that came to a head in the mid-1970s (sections V and VI).

There is no doubt that these three national symposia did much to consolidate the ideas and research protocols for the new field in the United States. They also provide such a complete and handy entrance to the literature that we can be content to describe primarily the general trends and key findings when we discuss these decades in the following section of this chapter.

There was a fourth national symposium held in 1975. It was under the auspices of Oregon State University at Corvallis, Oregon, and carried the title "Radioecology and Energy Resources" (Cushing 1976). It represents, to a degree, the merging of interests in radiation sources and radiation problems with other forms of energy generation.

Obviously, these symposia were not the only forces that contributed to the maturation of radioecology in the United States. There were hearings on fallout and on industrial waste disposal before the Joint Committee on Atomic Energy. In 1963, Merrill Eisenbud produced the first edition of his succinct and enormously useful book *Environmental Radioactivity* (Eisenbud 1963). Also in 1963, a conference on the Ecological Effects of Nuclear War was held at Brookhaven (Woodwell 1965). In 1965, one of the Hanford biology symposia, which was international in scope, considered "Radiation and Terrestrial Ecosystems" (Hungate 1965). In 1970, the American Chemical Society sponsored a symposium on "Radioisotopes in the Environment" (American Chemical Society 1970). This emphasized chemistry more than biology but considered many processes basic to the understanding of radioisotope behavior. Also in 1970, a symposium at the University of Minnesota on Nuclear Power and the Public (Foreman 1970), and a similar enterprise at the University of Wisconsin entitled "Student Conference on Nuclear Power and the Environment" (Carbon and Houlberg 1970) appeared. These both had sections devoted to environmental problems. In 1971, Eugene Odum wrote a chapter entitled "Radiation Ecology" in his much-used textbook *Fundamentals of Ecology* (Odum 1971).

The U.S. NAS-NRC had several committees active in the field of radioecology during this period. Their reports are, to a degree, basic to this and each of the following three chapters and will be quoted in some detail where appropriate. However, a formal listing at this point in our discussion may be helpful. The reports, including shorthand designation, are listed below.^(b)

1. NAS-NRC Report #551, *The Effects of Atomic Radiation on Oceanography and Fisheries* (The Revelle Report), 1957
2. NAS-NRC Report #655, *Radioactive Waste Disposal into Atlantic and Gulf Waters* (The Carritt Report), 1959

(a) Plants had, of course, been included in the other symposia but not under a special title.

(b) The author is indebted to Dr. Allyn Seymour, University of Washington, for helping provide this information.

3. NAS-NRC Report #658, *Consideration of the Disposal of Radioactive Wastes from Nuclear Powered Ships into the Marine Environment* (The Pritchard Report), 1959
4. NAS-NRC Report #985, *Disposal of Low-Level Radioactive Waste into Pacific Coastal Waters* (The Isaacs Report), 1962
5. NAS-NRC Report (no number); *Radioactivity in the Marine Environment* (The Rime Report), 1971

Finally, we can cite a 588-page bibliography on ecological aspects of the nuclear age prepared by the AEC and issued in 1972 (Schultz and Whicker 1972). Need we say more except to remind the reader that these same authors produced the two-volume book entitled *Radioecology: Nuclear Energy and the Environment* (Whicker and Schultz 1982)?

The international scene was comparably active. The emergence of reports from the classified literature to presentation at the Atoms for Peace Conferences has already been described. The first report of the United Nations Committee on the Biological Effects of Atomic Radiation (UNSCEAR) in 1962 carried a section on environmental aspects. The International Atomic Energy Agency (IAEA) in Vienna ran a continuing series of seminars, symposia, and reports beginning in 1960 and continuing to the present. Some of these are:^(a)

- Disposal of Radioactive Waste*, 1960
- Disposal of Radioactive Wastes in Fresh Water*, 1963
- Disposal of Radioactive Wastes into Seas, Oceans and Surface Waters*, 1966
- Practices in the Treatment of Low- and Intermediate-Level Radioactive Wastes*, 1966
- Disposal of Radioactive Wastes into the Ground*, 1967
- Management of Radioactive Wastes at Nuclear Power Plants*, 1968
- Environmental Contamination by Radioactive Materials*, 1969
- Environmental Aspects of Nuclear Power Stations*, 1970
- Population Dose Evaluation and Standards for Man and His Environment*, 1974
- Impacts of Nuclear Releases into the Aquatic Environment*, 1975
- Transuranic Nuclides in the Environment*, 1976
- Effects of Ionizing Radiation on Aquatic Organisms and Ecosystems*, 1976
- Biological Implications of Radionuclides Released from Nuclear Industries*, 1979
- Behavior of Tritium in the Environment*, 1979

The above list includes many quite large volumes. Thus, the amount of published work from IAEA alone is enough to establish radioecology as a very active field on the international scene.

An activity very nearly like the several American symposia occurred in Stockholm in 1966. Under the title *Radioecological Concentration Processes*, an international group filled 1,040 pages on this subject alone (Åberg and Hungate 1967).

For a field that started as highly classified work around Hanford and Oak Ridge, the above catalogue of American and international studies is most impressive. We can conclude beyond any doubt that radioecology has "come of age." Yet, the complexity of the environment and of ecosystems still leaves many questions unanswered. We devote the balance of this chapter to setting down the primary conclusions that have emerged and to reviewing relatively recent and current trends and some of the questions for the future. More will appear in later chapters.

(a) The full reference for each of these is given in the bibliography for this chapter.

V. The Later Years Around the Production Sites

In this section, we will attempt to summarize the major findings from the work, particularly in the United States, at the sites described as well as work along new lines and at new institutions.

The institutions named earlier were joined by others. A major addition was the biomedical program of the Lawrence Livermore Laboratory of the University of California. Starting early as a weapons-oriented laboratory, in later years it mounted a biomedical program with considerable environmental orientation. This was particularly concerned with a major outgrowth from the Atoms for Peace movement called Project Plowshare (chapter 14). Much of it concerns the Pacific Proving Ground and NTS, but their methodologies—particularly some aspects of their extensive meteorological effort—applied to work oriented around production sites as well.

In addition to those mentioned earlier, a major role in the oceanographic aspects was taken by Oregon State University and the Woods Hole Oceanographic Institute and their oceanographic vessels.

A. Generalizations

One of the first hopes of the radioecology enterprise as it bore on radionuclides was to describe the environmental behavior of each major group. When the work began, variability was so great that the hope for generalizations was considerably dampened. Fortunately, careful examination of the influence of physical factors such as climate and topography; chemical factors such as the inherent chemistry of the radionuclide and the nature of the ligands with which it might combine; the colloid and surface chemistry of the milieu, and the presence or absence of competing elements, the ecosystem properties, and the inherent characteristics of the biota involved did much to sort out the apparent confusion and randomness. Thus, by the 1980s, Whicker and Schultz (1982) were able to summarize the environmental behavior of specific groups of radionuclides and of key members of each group. This was developed from the world's literature and based especially on a series of reviews, which is given as note 2 to this chapter. They consider the nonmetals, light metals, heavy metals, noble gases, rare earths, and the actinides (Whicker and Schultz 1982, pp. 147-162). A very satisfactory overview can be developed from this compendium.

To make our cup really full, Whicker and Schultz got together a summary table of the ecological behavior of the important radionuclides in each category above. This is reproduced herewith as table 11.4. Some general patterns of behavior can be drawn from summaries like that given in table 11.4. The elements in the nonmetals category are all isotopes of essential nutrients. They are, therefore, readily assimilated and transported through food chains. Most of the light metal group are analogous (but not identical) to calcium or potassium and behave roughly like their analog. They, too, pass readily through food chains. The noble gases are, of course, unique and have essentially no nutrient analogs. They pass readily throughout the environment wherever substances in gaseous form can penetrate. The heavy metal group is much more varied, and behavior is less predictable and more dependent on chemical form and mode of biological exposure. Most heavy metals tend to deposit eventually in the sediments of aqueous systems or in soils. The rare earths of interest to us are generally poorly absorbed and poorly transported, as are the actinides.

There are, of course, considerable differences among members of a given group, and the categories therefore overlap. However, the broad outlines, based upon an enormous investment of time, effort, and resources, can be considered reasonably well established by virtue of this work.

B. Extensions and Generalizations from the Hanford Work

Near the end of the decade of the 1960s, the Hanford group produced a master plan for bioenvironmental work at PNL. The organization became the "Ecosystems Department," managed by Dr. Burton Vaughan.^(a) During a sixteen-year period, Dr. Vaughan and his colleagues in the Ecosystems Department were responsible for developing the biochemical and geochemical basis underlying many environmental contaminant phenomena. A new school of thought was developed around the concept of biological availability and the processes accounting for molecular speciation of contaminants. This work culminated in the E.O. Lawrence Award to Dr. Raymond E. Wildung for "particular contributions on plutonium biological availability through food chains and on nutrient availability in lake ecosystems (see chapter 15). This later period also saw the development of significant work on the role of radiation and heavy metal stressors in increasing disease in fish and shellfish. Particular mention should be made of work on immune suppression following low tritium radiation doses (see section VI F), work at the Marine Laboratory on metallothioneins induction and shellfish viruses, and work on the multiple etiology of columnaris disease (see section VI B).^(b,c) Facilities suitable for experimental work in both aquatic

(a) Richard Foster, who can be regarded as the father of the Hanford ecology programs, went to a post involving population radiation dose assessment, but his influence on aquatic biology never ceased. Herbert Parker was the grandfather of these programs.

(b) This and several other extensions, and updatings in this section, and in section VI were supplied by Dr. Vaughan as a result of his review of the manuscript. The author is grateful for these authoritative additions.

(c) In 1985, Dr. Vaughan became an assistant director of research at PNL, and the Ecosystems Department consolidated with both Geosciences and Atmospheric Sciences to form a large Earth Sciences Department with wide multidisciplinary capability.

and terrestrial biology were included in a new building constructed by AEC. This facility is pictured in figure 11.9A.

FIGURE 11.9A. Facilities for ecological research at Pacific Northwest Laboratory (Hanford) as they existed in 1964. (Courtesy of Pacific Northwest Laboratory.) The contrast to the original hutment (figure 11.1) is obvious.

Furthermore, the oceanographic and marine bioscience capabilities were consolidated and expanded with a laboratory at Sequim, Washington. Particular emphasis was placed on determining the bioavailability of contaminants, both radioactive and chemical. Research on the induction of metallothioneins in marine fish, isolation of these compounds, the range of their specificities, and the extent to which they protect from the toxic effects of heavy elements, all reached a high point of development at the laboratory at Sequim. This laboratory also pioneered in the development of methods for dealing with multiphase, complex mixtures such as petroleum, where fish, for example, may "see" a continuing shift in the "spectrum" of hydrocarbons they might be exposed to during a spill. A view of the new building at Sequim, built by Battelle, is shown as figure 11.9B.

We will be able to discuss only a few sets of generalizations from this work. Fortunately, the many symposia quoted in section IV provide ready access to aspects we cannot consider. A synthesis of PNL's environmental research on complex mixtures can be found in Fickeisen and Vaughan (1984).

FIGURE 11.9B. Battelle, Pacific Northwest Laboratories' marine research facility at Sequim, Washington, on Puget Sound. (Courtesy of Pacific Northwest Laboratory.)

1. Generalizations from Columbia River Studies

The work extended not only the length of the Columbia River below the reactors but into its estuary and the north Pacific Ocean many miles from the mouth of the estuary. Among the firm conclusions are the following:

- a. Despite concentration factors that might appear quite high,^(a) even people who consumed extraordinary quantities of resident fish would have reached no more than one quarter of the population dosage limit recommended by the ICRP. Since the discharges have been declining steadily since 1970, there is little likelihood of this amount being exceeded in the future. These figures stand in considerable contrast to the story, for example, of the Animas River cited above, a situation reflecting neglect in the early years.
- b. The more prominent radionuclides found in the Columbia River effluent were ^{24}Na , ^{32}P , ^{51}Cr , ^{64}Ca , ^{65}Zn , ^{76}As , and ^{239}Np . Several of these have short half-lives and disappear rapidly. In the ocean environment off the mouth of the Columbia, the important nuclides are ^{51}Cr and ^{65}Zn . Since ^{51}Cr has a

(a) Concentration factors can be very deceiving, since the base line in many freshwater environments is very low and frequently variable. Also, there can be no true concentration factor stated unless the system is in equilibrium or a steady state.

short half-life and ^{65}Zn has a moderately long half-life and is quite mobile, it is the latter that has attracted the most attention. (As we will see in chapter 12, complementary work with ^{65}Zn was being done at the Pacific Proving Ground.)

- c. A large portion of the radioactivity entering the river is combined with the sediments, particularly bottom sediments. This was obvious very early. Recently, a sophisticated analysis using mass spectrometry was carried out by investigators from Oregon State University and the Savannah River Laboratory. Beasley et al. (1981) measured the ratios of ^{240}Pu to ^{242}Pu and of ^{240}Pu to ^{239}Pu in sediment cores raised during August 1977 from the McNary Reservoir downstream of the plant and the Ice Harbor Reservoir on the Snake River, a tributary of the Columbia that had no reactor-produced plutonium. They could thus distinguish between plutonium arising from worldwide fallout and that from the Hanford reactors. Two items were of special interest. The radioactivity of the sediments in the region around McNary Dam indicated that significant depositions of reactor plutonium had occurred in this first major impoundment below the reactors. While easily measurable amounts of all radionuclides did traverse the length of the river and enter the Pacific Ocean, the degree of deposition in relatively local areas must be reckoned with in any estimate of hazard. Also, it was estimated that about a quarter of the total plutonium inventory in sediments behind McNary Reservoir came from the Hanford reactors. The rest was from global fallout.
- d. The Hanford effluents "tagged" not only river currents but biota in all compartments of the system. The movement of the Columbia River plume along the Pacific coast to the north of the estuary in summer and to the south in winter was clearly established; also the behavior of the Columbia River plume in the open Pacific could be followed and its depth measured (it was surprisingly deep at times). All of these findings have a bearing on any attempts to establish critical population groups and critical pathways. Indeed, important basic information on the physics, chemistry, and biology of complex freshwater, estuarine, and marine ecosystems developed from these bonus tracer observations from a vast unplanned experiment.
- e. There is a notable absence of biological effects in these aquatic ecosystem studies. Despite diligent searching, no biological effects could be found from either the radioactive or chemical pollutants present.^(a) For example, Nelson from the University of Washington studied effects on larvae of the Pacific oyster, considered a critical organism in this system. He used ^{65}Zn , ^{51}Cr , and ^{90}Sr - ^{90}Y , as well as stable zinc and chromium. In laboratory investigations, the concentrations of these elements required to produce abnormal oyster larvae were over a million times those found in the breeding areas such as Willapa Bay (Nelson 1972). Small wonder that effects were not established in the ecosystem.

The search for effects was continued, however, using numerous ponds and streams on the Hanford site. A summary paper by Emery and McShane (1980) gives a cogent review of the work and its results; the abstract follows.

(a) It would be foolish to conclude that there were no effects of any kind due to the complexities of the system. However, the fact that none were found in such extensive work is significant.

Limnological and radiological parameters were investigated in ponds and streams on the Hanford Site to develop general radioecological profiles. All but one aquatic system receive low-level aqueous radioactive wastes from nuclear facilities. The remaining system is a pond formed by surfacing groundwater and contains radioactivity as a result of evaporative concentration of naturally occurring radionuclides. Attempts were made to determine whether the amounts of radioactivity present in each aquatic system could be related to ecological variation occurring among them. Maximum dose from the sediments and nuclide concentrations in the water were used to differentiate these systems radiographically. While Hanford ponds and streams could be grouped into three nuclide content categories, only one system (100-N Trench) had dose rates exceeding 1 R/week. However, maximum α concentrations in Z-19 Ditch water and maximum β - γ concentrations in 100-N Trench water both exceeded 10^4 pCi/l.

These aquatic environments support populations of commonly occurring algae, macrophytes, invertebrates and in some cases, fish. Although the algal populations contain less variety in 100-N Trench and Z-19 Ditch, variety in other types of biota are not apparently associated with amounts of radioactivity. Community structures in these systems appear to be as diverse as those in the Columbia River but less diverse than in some offsite streams. The productivity of plant life, invertebrates and fish in these systems does not appear to be associated with the relative difference of nuclear waste contamination. Furthermore, their rates of productivity resemble those measured in aquatic environments not associated with nuclear activities. Since these ponds and streams cannot be clearly differentiated from offsite systems or among themselves on the basis of a general ecological profile, this survey provides no conclusive evidence that the nuclear wastes discharged into Hanford ponds and streams have affected the colonization, diversity and activity of biota that appear in them.

A significant ecological feature in the Emery and McShane study was the incorporation into its sampling design of both seasonal biomass change and spatial distribution of biomass for all major trophic levels. At maximum, vector transport of plutonium by all biotic routes off U-pond,^(a) the most highly contaminated pond on the Hanford site, was trivial, and it was exceeded only by the investigators in the process of removing their samples!

These findings are reassuring. No horrible mistake seems to have been made. Indeed, it is easy to find ecologists who will state that the building of dams and the elaborate systems for irrigation have done much more to the ecology of the Columbia River than the Hanford effluents did or ever could have, even had they been less well controlled. We must express appreciation once again to those far-sighted individuals who stimulated the research programs on the river and its biology and insisted on the most rigorous of controls.

Nevertheless, contamination does exist.^(b) There is a substantial reservoir of radioactivity in the sediments all along the river. These must always be considered in planning any major activities that would disturb them or, in the event of unprecedented high water, that might sweep up sediments deposited many years before. Fortunately, the passage of time contributes to the gradual decay of the radioactivity of these deposits.

2. Terrestrial Work at Hanford in the Later Years

A considerable portion of the later work at Hanford in the field of terrestrial ecology extended investigations we have discussed earlier and in other

(a) The U-pond has since been decommissioned.

(b) Its justification is not an appropriate subject here (see, however, Alverson 1972, p. 856).

chapters. There was continued interest in the dispersion and effects of iodine, ruthenium, and, as we will review later, of the actinides. There was considerable work on the passage of radionuclides through arctic food chains, particularly as developed by J. J. Davis, and of fallout radionuclides in the local environs as well as at the test sites. There were laboratory investigations of the solubilization of radionuclides deposited in soil and their uptake by plants (chapters 13, 15). There was continued follow-up of the movement of radionuclides in animal and plant populations indigenous to the site.

In 1969, it was evident to the PNL Terrestrial Ecology Section that environmental radiation doses at the Hanford site were far too low in native plants and animals for any radiation effect to be expected. While monitoring radioelement movement in fish and wildlife food chains continued at the Hanford site, the research staff in terrestrial ecology took a different course from that at Oak Ridge and Nevada Test Site. The Arid Land Ecology Reserve, a forerunner of the National Environmental Research Park (NERP) system was established. This was the first Department of Energy (DOE) site dedicated as a Federal Research Natural Area. The 110-mi² reserve was dedicated to the study of wildlife, and vegetational and water dynamics typical of semiarid regions. By 1983, over two hundred university researchers had collaborated in these studies, and some sixty dissertation studies had been sponsored. Apart from wildlife studies, one of the main contributions of the NERP program was to show how evapotranspiration and other vegetational features could be modified to minimize entry into food chains of radionuclides buried in soil.

In the wildlife area, Dr. Lee Eberhardt and his colleagues contributed a distinguished series of statistical studies dealing with population estimation and spatio-temporal considerations in the design of biological monitoring programs.^(a)

Special note should be taken of the Ringold Farms study. It provides an excellent model for onsite evaluation work. It began in mid-1962, and the results were published in 1965 (Nelson and Foster 1965). Ringold Farms is a small farming area (about five hundred acres) on the Columbia River about thirteen miles downstream from the nearest production reactor. Columbia River water is used for irrigation. It is also about thirteen miles downwind from the separations plant. It is the closest area of active farming to both facilities.

There had been regular sampling of air, water, and farm produce from the area. These, along with measurements of external radiation levels, permitted a calculation of the probable range of dose to the inhabitants using many assumptions regarding dietary habits, etc. The availability in 1962 of a whole-body counting facility and the cooperativeness of the twenty people living in the Ringold Farms area provided an excellent opportunity to double-check the calculations and also to measure a group with presumably a higher-than-average chance of exposure. Zinc-65, ¹³⁷Cs, and ¹³¹I were particularly emphasized in the whole-body counts. As a check on isotopes like tritium, plutonium, uranium, etc. that would not show easily on the whole-body counters of the day, bioassay measurements were made on twenty-four-hour urine samples.

The whole-body counts indicated little difference in ¹³⁷Cs and ¹³¹I contents from those seen in others subjected to fallout radionuclides alone. Zinc-65 was also present in the subjects. All values were far below maximum permissible body burdens. The highest was iodine in the thyroid, which reached about 4% of the permissible level.

(a) This and the previous paragraph were supplied by Dr. Vaughan.

The bioassay measurements showed ^{32}P at levels of 1% to 5% of the NCRP maximum permissible body burdens (chapter 16) and no ^3H or ^{239}Pu . There was a small amount of uranium that came from the well water.

This study was necessarily small in number of subjects. However, it was consistent. The dietary habits of the subjects were known exhaustively. The usefulness of a whole-body counting survey for evaluation of environmental contamination was clearly established, and the correlation with doses estimated from intake values was reasonable.

A related set of studies involved the whole-body counting of thousands of school children in Richland, Washington, and the Tri-Cities area, as well as the use of portable counters for measurements of fishermen and extensive modeling for calculation of population dose. This was aimed first at checking out food-chain predictions (Foster 1979) and should be associated primarily with Dennis Harr, J. F. Honstead, and J. K. Soldat. (a) Battelle-Northwest reports and a paper at a Health Physics Society midyear topical symposium can be cited (Soldat and Honstead 1968; Soldat 1969; Honstead 1969 and 1970). The levels found were no cause for concern, and the information was primarily useful for checking intake routes. (b)

Later, the Hanford work developed into quite generalized modeling for estimating population doses from environmental contamination of many sorts (Soldat 1979). The original model had seventy-two parameters! Gradually, it was simplified by elimination of the less important factors, and it was computerized. The effect of many inherent parameters of the individual, such as age, was introduced, as were different routes of entry, different dose regimes (chronic versus acute), etc. An example of a typical report coming from this program is the one by Hoenes and Soldat prepared for the Nuclear Regulatory Commission (NRC) (Hoenes and Soldat 1977). This and other compilations from the group have been extremely useful to environmentalists, and they represent an important way in which operations and methodology generated for site-specific problems have been generalized for use in many situations (see section VI).

Finally, it should be noted that the Hanford group (now, of course, Pacific Northwest Laboratory, operated by Battelle Memorial Institute) got involved with the development of criteria for the decommissioning of sites no longer needed or used for nuclear activities (Soldat 1979). We will discuss this general activity in connection with Oak Ridge's later contributions.

- (a) Some of the original plans for environmental monitoring came from Jack Healy and Carl Gamertsfelder, who were in key positions in the earlier Hanford organization. Dennis Harr contributed considerably in the developing stages of the population exposure work (Soldat 1979), even though his name does not appear on the publications cited. The same applies to Karl Herde, whom we quoted in an earlier section.
- (b) An interesting sidelight on the early development of the bioassay techniques that preceded the wholesale application of whole-body counting has been provided by Karl Herde (1978). In 1947, Healy and the control group in the 200-West area (which included Herde) were having great difficulty establishing reliable techniques for bioassay of urine. They kept encountering high "background" counts, not only in the potentially exposed individuals, but in terrestrial and aquatic animals on the site and off, and in "controls." Since this was in the days before easy spectroscopy, they were doing gross counts and could not identify the isotope concerned. Suddenly, after an intensive search of the literature by Healy, it dawned on the group that the activity came from the body's natural content of ^{40}K !

C. Extensions at Oak Ridge

The environmental work in the later years at Oak Ridge was qualitatively much like what we discussed in section III. Quantitatively it boomed. In figure 11.10A, B, we see this transformation. Figure 11.10A pictures the "Ecology Program" of the Health Physics Division as it stood in summer 1955. In figure 11.10B, we see the "Ecological Sciences Division" standing before their new building in summer 1978. It is obvious that the Oak Ridge environmental program had become a strong force for all ecology.

FIGURE 11.10A. Oak Ridge Ecology Program, summer 1955. (Courtesy of S. Auerbach.)

A measure of the contributions made is possible from a list of publications prepared in 1979 (ORNL 1979). This list is chronological from 1956 and reaches a grand total of 1,334 publications by the end of 1978, with an additional 11 indicated as "in press." Unfortunately, this is purely a chronological list. Anyone wishing to find papers on particular subjects is forced to dig.

1. Aquatic Programs

The Clinch River, as we saw in section III, presented some problems comparable to the Columbia, some that were rather different. Generalizations can be gleaned from a comprehensive report of the Clinch River study issued in 1967 (Struxness et al. 1967).^(a) Some of these are:

(a) By this time, and in subsequent work, the scene had actually moved out into the Tennessee River and went for many miles below the Clinch River per se. Thus, the study is more comprehensive than the title indicates.

FIGURE 11.10B. Oak Ridge Ecological Sciences Division (now Environmental Sciences Division), summer 1978. (Courtesy of S Auerbach.)

- a. The river acted primarily as a tube for many radionuclides. Virtually all of the ^{90}Sr and ^{106}Ru entering the Clinch River passed through the river system in the water phase. It went as far down as Chattanooga, the last downstream station, 118 mi downstream from Oak Ridge, with relatively small changes except for radioactive decay.
- b. While these nuclides were in the water phase, they were not necessarily in solution. Much activity was attached to and was retained by very fine suspended particles in the river. (Note: These particles were not removed by high-speed centrifugation.)
- c. Most of the ^{137}Cs was associated with larger-sized suspended solids in White Oak Creek and Clinch River but was in solution or associated with very fine solids by the time it reached the Tennessee River.
- d. It was calculated that over 7,000 Ci of mixed fission products had been discharged into the river over a fifteen-year period.
- e. Of the above amount, about 200 Ci, or only about 1.5% of the total radioactivity released since 1944, could be accounted for in the bottom-sediments of the Clinch River. This stands in considerable contrast to the deposits in sediment of the McNary reservoir below Hanford. It reflects presumably the fact that no impoundment interposed. The information was based on analyses of core samples.
- f. There were some differences in the distribution of nuclides, with a definite loss of ^{137}Cs between the upper and lower reaches of the river, but not of the other primary radionuclides measured (^{60}Co , ^{89}Sr , and ^{106}Ru). There

- were: some differences in all of them between the more rapidly flowing upper reaches and the slower lower reaches of the river. There was very little deposited except along the sides of the stream in the former, deposition over the entire stream bed in the latter.
- g. All of these factors influence, of course, the details of the biological responses. Nevertheless, some generalizations regarding biological aspects can be made.
 - h. The white crappie was selected for study of uptakes in local fish, since fish-tagging showed that it did not migrate very far in the river.
 - i. River clams were found to be good indicator organisms for studying uptake and turnover of radionuclides and the extent of uptake at a given location. The clams are, of course, essentially immobile.
 - j. There was essentially no loss of ^{90}Sr from fish bones or clamshells, and the concentrations were directly proportional to the amounts in river water. By contrast, the retention half-time in flesh of the white crappie was on the order of one hour.
 - k. Effects were not seen in any of the biomass organisms studied, except for chromosome aberrations in *Chironomus* larvae. While these appeared, they seemed to be eliminated from the population by processes of natural selection and thus seemed not to represent permanent damage.
 - l. In the consideration of possible exposures, it appeared that ^{90}Sr and ^{137}Cs were the critical radionuclides and that drinking water and fish were the critical exposure pathways. Using these, total doses to teenage individuals (the critical age group) were calculated to be 3.2 and 0.45 rem from the Clinch and Tennessee Rivers, respectively.^(a) These figures are about one-tenth of the maximum permissible dose accepted at the time (Struxness et al., 1967, pp. 4-5).
 - m. For future projections, it was concluded that monitoring of the water and fish would be sufficient to keep track of what was going on in the river, with sampling of bottom sediments given a lower priority. Naturally, any unusual or extreme conditions would require reestablishment of the more detailed routines.
 - n. The Clinch River study actually involved six major technical and professional agencies, not just the Oak Ridge National Laboratory and the AEC. The authors of individual papers and the steering committee are convinced that such broad participation (and everyone contributed substantially) helped greatly to assure the success of the work. The agencies involved are listed as note 3 at the end of this chapter.

2. Terrestrial Programs at Oak Ridge in the Later Years

The substance of the Oak Ridge terrestrial ecology program was delineated in section III. Additional information was gathered in later years along the same lines as reviewed in the bibliographies and symposia already cited. (The most recent is by Klement and Schultz 1980.) New aspects included emergency planning for the Clinch Valley (Auxier and Chester 1973); several contributions to

(a) This difference may seem inconsistent with the earlier generalization that the isotopes went through the river system like a tube. We must remember that the water volume in the Tennessee River is considerably increased over the Clinch.

ecological considerations in siting power reactor plants (e.g., Auerbach 1970; Auerbach et al. 1971); Project Plowshare, which we will examine in chapter 14; and important ecological analyses of a variety of sites.

The calculation of dose to man from potential or actual environmental contamination gradually took on an identity of its own. Under the Health and Safety Research Division (new name for the Health Physics Division); a section called "Technology Assessments" grew under the capable direction of Paul S. Rohwer. The activity began as part of Project Plowshare (chapter 14). By the mid-to-late seventies, it had expanded to include over forty people and a broad program that included biotransport and dosimetry models, atmospheric transport research, alternative fuel cycle technologies, assessment of the radiological problems of mining and milling of uranium and thorium, development of environmental impact statements, radiological surveys of inactive sites or formerly utilized sites (see below), and a variety of special projects.^(a)

The radiological surveys of inactive and formerly utilized sites deserve special attention since they illustrate graphically the legacy that poorly controlled activities can leave.^(b) Figure 11.11 gives the geographical distribution of the more important of these survey sites as of 1978.

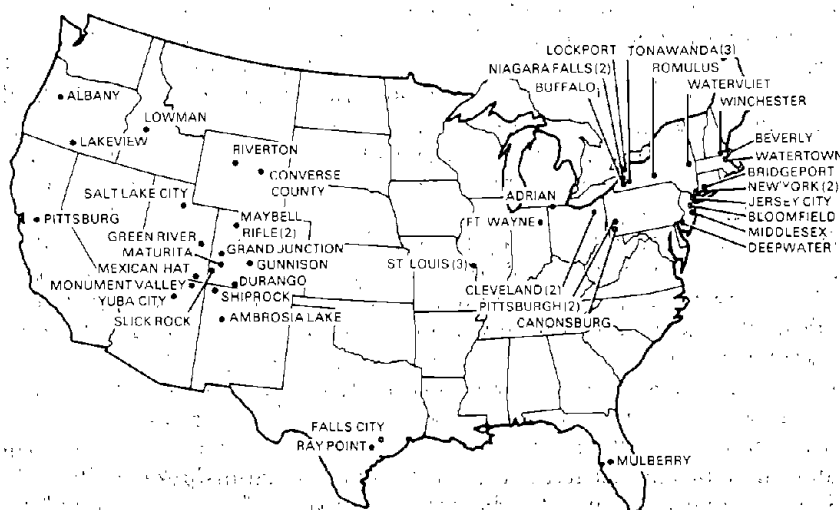

FIGURE 11.11. Geographical distribution of radiological survey sites (from ORNL 1979).

Some of these were uranium mills. However, many of those in populated areas represent old sites used during the MED days, even before, as well as, in

- (a) To a degree, the ORNL growth into assessment was parallel to that we have already mentioned at Hanford.
- (b) None of these are comparable in any degree to the notorious toxic waste dumps left by chemical industry operations (e.g., Love Canal on the Niagara Frontier), but they have the same implications qualitatively.

some cases, by the AEC in the 1950s. These had been turned back to the public domain for other uses. In the last days of AEC, i.e., 1974, a program was initiated to determine the condition of these sites. It was continued under AEC's successor agencies, ERDA and DOE. The results ranged from finding of only very localized contamination within some bunkers used for storage of pitchblende at the former Seneca Army Depot in Romulus, New York, to widespread and potentially serious contamination at sites such as the former VITRO Rare Metals plant at Canonsburg, Pennsylvania, and the former Horizons, Inc. Metal Handling Facility at Cleveland, Ohio (DOE 1977, 1978, 1979a,b; ORNL 1978).^(a) With over one hundred sites to look at, the personnel from the ORNL Health and Safety Research Division were busy throughout the country. Most of the sites were found to be within prescribed limits for exposure of the public. Some were from a little to considerably over the established limits. The worst problems occurred where the radium-containing portion of uranium ores had been discarded (see earlier discussion of uranium mills), particularly sites such as the one at Canonsburg, which had been used as early as 1911 to 1922 and 1930 to 1942 to extract radium from carnotite ore or scrap materials. Here there were significant amounts of ^{222}Rn in the buildings, of radon decay products on surfaces, and of ^{226}Ra both as a surface contaminant and in the ground beneath the buildings and around the site. The latter contributed significant gamma doses, while the airborne radon daughters in some of the buildings might go as high as 2 Working Levels (chapter 3).

All of this has led to many dilemmas regarding remedial action, particularly agreement on suitable criteria. The levels for recommending remedial action can be moved at least an order of magnitude by differences in assumptions regarding metabolic constants, e.g., the absorption from the gastrointestinal tract (more in chapter 16). Thus, the question of the relative availability of radionuclides that have passed through an environmental chain or just resided in the environment for long periods has become important enough to stimulate considerable research, at Oak Ridge, at Hanford, and at other places.

In conclusion, we can state with assurance that the radioecology work at Oak Ridge in the later postwar years has been qualitatively and quantitatively very significant. Perusal of the many literature reviews cited herein will provide further details.^(b) We will learn more of the research in chapters 13 and 15.

D. Work at Other Laboratories in the Later Years.

Since the discussions in the balance of this chapter and most of those in the subsequent chapters concerning the environment will not be organized laboratory by laboratory, this section is written for the convenience of the reader wishing to spot particular laboratories and their general orientation toward

(a) This author is indebted to Dr. Paul S. Rohwer, ORNL, for making copies of these reports available.

(b) The recent revelations and polemic regarding the release of large quantities of mercury at Oak Ridge (Marshall 1983) led to the conclusion that vigilance cannot be relaxed, and also to the conclusion that chemical waste problems in the United States are probably much more critical for the future than radioactive wastes, except for the nagging problem of spent reactor fuels.

radioecological work in the years from the midsixties on. The descriptions are mostly cryptic, since details appear throughout other discussions. These are, of course, in addition to PNL and ORNL, already described.

1. Brookhaven National Laboratory

The primary involvement of BNL with radionuclides in the environment was its continuing (twenty-five years) in-depth study of the inhabitants and environment of the Pacific Proving Ground. The work resided largely in the Medical Division until very recently. With increasing emphasis on dosimetric problems and retirement of some key medical people, the center of gravity has shifted to the Safety (Health Physics) Division. This work is discussed in chapter 12.

2. Health and Safety Laboratory, New York

The influence of this group on fallout measurements and implications will be apparent in chapter 12. Its role in the radon and uranium miner saga has already been told (chapter 3). Its influence on investigations of radiation problems around mill tailing sites was expanded during this period to consideration of the elevated radioactivity from uranium, radium, and radon around sites of phosphate rock mining and handling. Very recently, they have devoted attention to the questions raised by radon levels in buildings. As always, HASL has been especially contributory to the development, calibration, and operation of instrumentation and as a voice of experience in many of the projects.

3. Idaho Falls Laboratory

With its vast and remote areas, the Idaho Falls facility was an excellent site for field tests of a special nature that could not be easily accommodated at the NTS. These will be reviewed in chapter 14. It, too, has contributed much to methodology, especially radiochemical analysis procedures.

4. Los Alamos Scientific Laboratory

As in the earlier years, Los Alamos's primary orientation to environmental work was toward the tests (chapter 12). This included special interests in plutonium contamination (chapter 14). There was further work on liquid waste discharges and movement of plutonium and cesium in soils of the Los Alamos environs (Hakanson and Bostick 1976; Nyhan, Miera, and Peters 1976).

Because Los Alamos was among the earliest laboratories to have a whole-body counting facility, much work was done on identifying the body burden of fission products in the local and general population. Measurements in the Los Alamos population, begun in 1955, were continued for two decades.

In the 1973 annual report, we find an Environmental Studies Group was identified by name and a proposal made for a national environmental research park at Los Alamos. Radioecology studies of liquid waste disposal areas and of the Trinity bomb site (chapter 12) are mentioned. In 1974, we find description of the elaborate wind-tunnel apparatus used for determining resuspension of surface contaminants (chapters 14 and 15). In 1976, we find a fairly detailed account of ecological studies on uranium (Hanson and Miera 1977, 1978).

The uranium studies represent a classic onsite study. Over a thirty-three-year period, over 100,000 kg of natural and depleted uranium had been dispersed^(a) at one location on the Los Alamos grounds, E-F Site. Uranium concentrations in soil and biota indicated that only very small amounts of the material had moved "any appreciable distance" from the point of origin. An effects study concentrated on invertebrates, mostly ticks and mites living in the area. The areas of highest uranium activity (as high as 41% uranium in solution) showed significantly lower populations of these insects than control areas. Whether this represents a chemical or radiological effect is not discussed.

We will see more of Los Alamos work as we proceed.

5. Lawrence Livermore Laboratory

In addition to its large involvement with the NTS and Pacific Proving Ground, the Lawrence Livermore Laboratory did various site-oriented studies. For example, they looked at the interactions between radionuclides in the discharge canal of the Humboldt Bay Power Plant near Eureka, California, and oysters in the canal. They found behavior indicating binding to particles in the sediment and an important role of these in the accumulation of some, but not all, of the nuclides in the oysters (Harrison, Wong, and Heft 1976a,b). They calculated the radiological dose to man through the marine pathway at this same reactor (Noshkin, Robison, and Harrison 1976). Besides their large involvement with plutonium and the actinides in the environment of the test sites, they considered global problems and some specifics such as ^{238}Pu from the testing of SNAP devices (Systems for Nuclear Auxiliary Power) in the waters near San Clemente Island, California (Noshkin et al. 1981). Details in later chapters.

6. New York University

The New York University (NYU) study of the Hudson River estuary is one of the longer-standing, more comprehensive surveys of a power reactor site. It began in 1964 and is continuing. It extends from the mouth of the Hudson River to a considerable distance upstream from the Indian Point Reactor, which is about forty-two miles north of New York City. The average flushing time of the estuary is about thirty days, slow in comparison with the Columbia and Clinch Rivers, except for the impoundments, but rapid in comparison with many lakes.^(b) The principal nuclides released range from 725 Ci of tritium to less than 0.01 Ci of ^{90}Sr per year (in 1971). The most important ones are ^{137}Cs , ^{134}Cs , and ^{54}Mn . The tritium, while initially present in large quantity, is rapidly exchanged and of much lower toxicity (see section VI).

The development of the NYU work can be followed in annual reports and occasional published progress reports (Lentsch et al. 1970; Wrenn et al. 1974). The easiest source is a pair of review papers given at a conference on radionuclides in the aquatic environment held at the University of Rochester (Jinks and Wrenn 1976; Wrenn and Jinks 1976). The first describes primarily the transport of radiocesium and modeling of same. The second is a broad review of the

(a) This was not dumping, but the result of a "dynamic testing program" with high explosives.

(b) Mean retention time in Lake Superior is, for example, 189 yr; in many smaller lakes, it is on the order of months to years.

work on the Hudson River estuary and dosimetric implications from it and many other aquatic environments in the United States into which nuclear fuel cycle effluents have been deposited (e.g. Colorado River, Animas River, Lake Michigan and other Great Lakes, Mississippi and Missouri Rivers).

The estuarine environment is especially interesting as the NYU people found, because the water varies in salinity. In periods of rapid river flow, the water near the Indian Point Reactor may be nearly fresh. In periods of low river flow, the tidal exchange brings salt water much further inland, and the water near the reactor may contain enough additional cations to influence greatly the combination of radionuclides with suspended particles. Jinks and Wrenn showed that the percentage of ^{137}Cs and ^{134}Cs in the dissolved state at Indian Point varied from less than 20% when the water was fresh to over 90% when chloride concentrations exceeded 2 g/l. (The balance was attached to particles.) The relationship was logarithmic, and distribution coefficients could be calculated.^(a) There was also a considerable difference in the rate of desorption of cesium from bottom sediments at different times of year. The maxima were in the warmer months and represented again the change in distribution coefficient with concentration of ambient cations. These phenomena are, of course, reflected in the concentrations of radionuclides in the biota and in the calculated doses to humans. The dose is not at all a constant value, even if other variables remain constant. These phenomena, of course, pertain to all estuaries, not just the Hudson River, but the variations in salinity may be greater in it than in some others. Nevertheless, mean or maximum values can be used and potential hazard estimated.

The time course of the mean concentration of ^{137}Cs in sediment water and biota over a ten-year period is given in figure 11.12, taken from the review by Wrenn and Jinks.

Note that the minimum activity in the water corresponds with the end of the major fallout contributions, and that, like the other river systems described, the radioactivity of the bottom sediments rose steadily throughout the period. Although fish and aquatic plants had about the same content, the fish were the major route to man. Assuming consumption of 30 g of the fish per day, the calculated whole-body dose to man from all of the reactor nuclides in the Hudson River was 0.19 mrem/yr for 1971-1972 (Wrenn et al. 1974). Being on the shoreline at the nearest beach for 200 hr/yr would contribute 0.06 mrem/yr and swimming for the same period at the same place about 0.01 mrem/yr. These can be compared to allowable annual doses to the surrounding population of 3 mrem to the whole body or 10 mrem to any individual organ (Code of U.S. Federal Regulations, 10 CFR Part 50, Appendix I, September 1975).

The Wrenn-Jinks analysis proceeds to other reactors, both boiling-water and pressurized-water types, and other bodies of water. It concludes that radio-cesium will be the critical radionuclide in all fresh waters, except if a drinking water intake is near the source of the contamination. In this event, ^{131}I may be the critical nuclide. We see again in the NYU work that an analysis begun around a single site can evolve into general population dose considerations.

Incidentally, Wrenn and Jinks point out that in many systems, such as mining and milling, ^{226}Ra can be the critical radionuclide and should not be forgotten

(a) Another way of expressing the phenomenon is by relating the biological accumulation coefficient to the concentration of potassium. Jinks and Wrenn (1976) do this for several aquatic systems.

FIGURE 11.12. Cesium-137 content of sediment water and biota in the Hudson River: averages of 1962–72 along with fallout and reactor inputs. The increase in reactor releases (March 1971–March 1972) was due to leakage between primary and secondary cooling systems. These have remained at a constant lower level since upgrading of the radwaste system. (Redrawn from Wrenn and Jinks 1976. Reprinted with permission of Butterworth Publishers, Stoneham, Massachusetts, copyright 1976.)

in our zeal to measure fission products and activation products in connection with the nuclear fuel cycle. We have seen ample evidence of this fact already.

7. Rocky Flats Plant

A large plutonium fabrication facility was built by the AEC in the 1950s and was operated by the Dow Chemical Company at a site near Golden, Colorado, in Jefferson County, not far from Denver and Boulder. There were small routine

releases of plutonium from the plant stacks from start-up in 1954 because the filter system was not and could not be absolute. (Some very small particle sizes could get by.) The extremely pyrophoric nature of plutonium under conditions suitable for machining led to occasional fires despite elaborate precautions. There were major fires at the plant in 1957 and in 1969 that destroyed the integrity of the filter system and released significant quantities of plutonium to the environment. Measurements of plutonium in the soil and in water were carried out by local staff initially, then concerned groups from surrounding university and governmental laboratories began looking for plutonium. Edward Martell at the National Center for Atmospheric Research near Boulder, who had already had considerable contact with research involving radioactive materials, demonstrated the presence of plutonium in soil around the plant. He appears to have been an important force in the development of a subcommittee on Rocky Flats under the Colorado Committee for Environmental Information (1970). Also, a report was prepared (as a memorandum to the files) by the ESSA Research Laboratories (Dickson and Start 1970). The environs of the Denver metropolitan area were much closer to the plant by 1970 than when the site was selected and the plant built. Between that and the reputation for toxicity attributed to plutonium, the contamination around Rocky Flats became a cause célèbre.

As a result of all this, the experts from the Health and Safety Laboratory in New York were called in, and many measurements were made, particularly of soil samples and soil cores. There was clearly plutonium about, and, on the basis of isotopic ratio measurements, Rocky Flats plutonium could be identified (Krey and Hardy 1970). However, it turned out that the highest concentrations were not downwind of either the 1969 or the 1957 fire. They lined up squarely with leaking barrels of cutting oil laden with plutonium and stored out-of-doors (Krey and Hardy 1970). The concentrations were not an immediate danger to health, but were uncomfortably close to or even above the new standards then being set by the Environmental Protection Agency (EPA). It was decided on a somewhat ad hoc basis that inhalation was the primary hazard.

At a symposium on environmental plutonium held at Los Alamos in 1971, Hammond from the Rocky Flats plant presented data on the routine releases and the total amounts of plutonium from the uncontrolled releases. He also told the story of the cutting oil drum storage and the genesis of what gradually became something of a controversy between Martell and his measurements and measurements by the plant and by HASL (Hammond 1971). In 1972, the Martell group made their procedures and findings generally available in a publication (Poet and Martell 1972). They looked at surface waters and sediments as well as soil. Soon Krey published revised figures (Krey 1974), and Poet and Martell responded (Poet and Martell 1974). However, the differences were mostly matters of details of the origin of and depth of penetration of the plutonium, etc.

A total inventory and further details were made available by HASL in 1976 (Krey 1976). The integrated figures showed 3.4 ± 0.9 Ci of $^{239-240}\text{Pu}$ were deposited from Rocky Flats on public and private land.

There was a rash of interest in the particle size distributions in the soil because the chance of redistribution by wind was much greater for smaller than for larger particle sizes. Much of this work was done by Dow Chemical Company in-house.

The HASL and related reports indicated that the plutonium had probably penetrated deeper into the soil around Rocky Flats than at the NTS (chapter 14), e.g., as far as 13 cm with sizeable amounts below 5 cm. This led to gradual

interest in possible percolation into water supplies and into the ponds around the plant. Figures for plutonium content of water appeared in the draft environmental impact reports for the Rocky Flats plant site developed for the Colorado State Health Department in 1973 and for ERDA in 1977. The concentrations in water were below current federal standards, but they were not below standards being proposed at the time to account for changes in the valence state and thus solubility of plutonium when water is chlorinated for drinking purposes (Larsen and Oldham 1978).^(a)

The people from Hanford decided to investigate the behavior of plutonium in several ponds and two creeks near the Rocky Flats plant (Paine 1980), with particular emphasis on its possible export from the site to water supplies.^(b) As in the other studies, sediments were the major site for plutonium deposition, and it tended to stay there. Fish flesh and bone showed no levels above the minimum detectable. Some varieties of plankton discriminated against plutonium, but other biotic components, such as the phytoplankton mixture known as seston (Paine 1980), showed high concentration ratios. This work concluded that there is no direct evidence that concentrations of plutonium observed will result in a biological hazard to humans through the ingestion route; but that studies should continue.

Despite this relatively negative conclusion, C. J. Johnson of the Jefferson County (Colorado) Health Department^(c) mounted an epidemiologic evaluation of the population. He designated groups enclosed by different isopleths of plutonium concentration, viz., 50 to 0.8 mCi/km², 0.8 to 0.2 mCi/km², 0.2 to 0.1 mCi/km², and a control population outside of the lowest isopleth. Populations were over 150,000 in each area. In a preliminary report delivered at the Sixth International Congress of Radiation Research (Johnson 1979), he concluded that there were significant increases in age-corrected leukemia death rates in the more contaminated areas and an age-corrected, age-specific increase in death rate from lung cancer. He also reported an increase in the rate of incidence of testicular cancer. Other entities, such as bone cancer, showed no significant difference, while the rate for congenital malformations was said to be marginally higher.

Some of these results, like the increase in leukemia incidence, are not characteristic of the effects of plutonium seen in animals. Like many epidemiologic studies covering a relatively short period, and source terms that are subject to many uncertainties (as freely admitted by the authors), these conclusions have been questioned. Some of the staff at the Lovelace Inhalation Toxicology Research Institute (see chapters 9 and 10), viz., R. G. Cuddihy, W. C. Griffith,

(a) At about this time, and partly because of the Rocky Flats events, there were several proposals for fairly drastic reduction of the standards for population exposures to plutonium and the transuranic elements. Myers (1972) concentrated on the deposition of the insoluble oxides in pulmonary lymph nodes and suggested, as have others (see chapters 9 and 16), that they should be the "critical organ" rather than lung. By a quite different approach, Morgan (1975) aimed at a similarly lower figure. They were 67 and 170 pCi versus the occupational standard of 0.04 μ Ci and a population standard of 1/10, 1/30, or 1/100 of this.

(b) This was like the work around the Hanford ponds already reported and can be considered a parallel comparative study. See Emery, Klopfer, and McShane (1980) and Emery and Klopfer (1976).

(c) The Colorado Regional Cancer Center, the Division of Vital Statistics of the Colorado Department of Health, and others contributed.

and R. O. McClellan, prepared a formal review as an "in-house" DOE document (Cuddihy, Griffith, and McClellan 1979). P. W. Krey at HASL introduced some new information that would modify the contours fairly sharply in some instances (Krey 1979). For these methodological reasons and because of the unusual pattern of cancer distribution noted, the reviewers believe that there may be some artifacts in the analysis. Also, they point out that fallout radioactivity contributes much more to the total radiation doses in the Denver area than does plutonium from Rocky Flats. Thus, the operation can be regarded as in the category of "picking fly-specks out of pepper."^(a)

Recently, a group of epidemiologists at Harvard, at a private concern in Chestnut Hill, Massachusetts, and at New York University (Dreyer et al. 1982) concluded that the total dose from transuranic contamination of the area around Rocky Flats is so far below natural radiation background and that from global fallout that the "statistical power" of an epidemiologic study would not be sufficient to support such an effort. Others have concluded that the data warrant concern even though they require confirmation and advise a reanalysis by better methods and over much longer time periods.

No information has come to light on whether or not any further epidemiology work is being attempted. The Rocky Flats story will undoubtedly continue into the future. Whatever the final answer, there seems little doubt that the plant has been made more environmentally safe. We can be sure it will be watched with a baleful eye by the local population.^(b)

8. Savannah River Plant

The work at Savannah River in the later postwar decades included the movement of tritium in the estuary of the river, plutonium behavior in the environment, and a continuation of the type of work described in section III. A few reports will come up in the specific topic section to follow. The reader is referred to the many reviews already cited for additional work.

VI. Special Topics

Before we can proceed to other aspects of environmental research concerning radionuclides, we must pause for a brief summary of some special subjects that have important niches. Some of them are closely related to work around the production sites. Others are quite general. Thus, this section fulfills the survey functions of this chapter as much as its orientation to the production sites.

A. Marine Radioecology

It is obvious from the materials we have already reviewed, and will be even more obvious as we proceed through these chapters on environmental aspects of radionuclide research, that the twin problems of fallout from weapons tests and potential or actual disposal of radioactive wastes have required major research efforts on marine systems. These have become sufficiently organized and idiosyncratic to justify the designation of "marine radioecology."^(c)

(a) This terminology is that of this author, not that of the reviewers.

(b) It is reported that Dow Chemical decided to bow out as contractor because of the continuing problems of public relations.

(c) The IAEA organized many symposia embracing aquatic environments (IAEA 1960, 1963, 1966a,b, 1968, 1969, 1971, 1975, 1976a,b, and 1979a,b).

No doubt the field began with the work at the University of Washington Applied Fisheries Laboratory. Perhaps the first time the field received an identity of its own was with the 1957 report of the U.S. NAS-NRC entitled, *The Effects of Atomic Radiation on Oceanography and Fisheries* (1957). Clearly, marine radioecology has a much larger component concerning the kinetics of transport of substances in the sea and perhaps less conventional ecology than other varieties of marine ecology. In the early reports, it was clear that the presence of new, manmade radioactive materials in the sea allowed a gigantic tracer chemistry experiment with implications to the fundamentals of the transport processes in the sea. In fact, Craig (1957) suggested that isotopic tracer techniques could characterize physical processes in the sea and atmosphere; and Folsom and Vine (1957) suggested that water masses could be tagged by addition of fairly substantial quantities of radionuclides (Operation "Hare and Hound," for example). Obviously, the same can apply to large-scale biological experiments (Revelle and Schaefer 1957; Schaefer 1957).

It must be remembered, of course, that the sea already has enormous quantities of natural radionuclides such as ^{40}K , ^{14}C , ^{87}Rb , and uranium and thorium isotopes. Even the apparently large quantities added by humans are very small by comparison. They will not alter the physical and chemical properties of seawater, except locally. Indeed, were it not for concentration in organisms by adsorption (as of polonium on the giant kelp described in chapter 4) and by metabolic processes, the dilution factors would make the additions inconsequential.

What of the much discussed concentration possesses?(a) A tabulation of historical interest taken from a paper by Krumholz at the University of Louisville, Goldberg at Scripps Institution of Oceanography, and Boroughs at the University of Hawaii is given as table 11.5.

It is clear that the concentration factor varies greatly among chemical species, among organisms, and between soft and skeletal-type tissues. Much of marine radioecology has involved further elucidation of these factors, the reasons for the differences, and how they can be used to estimate radiation dose. The book by Polikarpov (1966) from the USSR devotes considerable space to these matters, including detailed analysis of the behavior of major groups of elements and specific elements of interest. The Stockholm symposium on radioecological concentration processes goes into still more detail to the tune of over one thousand pages (Åberg and Hungate 1967).(b)

A few generalizations can be made regarding marine radioecology that are worth keeping in mind for subsequent chapters. These are in addition to those made in section V A and apply only to the marine environment.

1. Organisms at the first trophic level (e.g., simple organisms) take up radionuclides primarily in the ionized state or by adsorption on body surfaces. Usually the elements most concerned are those with counterparts in the nutritional scheme.

(a) If the amount in the biological material is less than the amount in the medium, this same ratio gets called a discrimination factor. There are fewer of these in the marine than in the terrestrial environment. (See earlier caution regarding derivation and use of these factors.)

(b) Much can be learned by simple perusal of this volume. The research involves some very general and some very specialized environments (terrestrial, freshwater, and marine) and it is all concerned with transport of materials, primarily radionuclides.

TABLE 11.5. Approximate Concentration Factors of Different Elements in Members of the Marine Biosphere. The concentration factors are based on a live weight basis.

Element	Form in Seawater	Concentration in Seawater (micrograms/l.)	Algae (Non-cal-careous)	Concentration Factors			
				Invertebrates		Vertebrates	
				Soft	Skeletal	Soft	Skeletal
Na	Ionic	10 ⁷	1	0.5	0	0.07	1
K	Ionic	380,000	25	10	0	5	20
Cs	Ionic	0.5	1	10	—	10	—
Ca	Ionic	400,000	10	10	1,000	1	200
Sr	Ionic	7,000	20	10	1,000	1	200
Zn	Ionic	10	100	5,000	1,000	1,000	30,000
Cu	Ionic	3	100	5,000	5,000	1,000	1,000
Fe	Particulate	10	20,000	10,000	100,000	1,000	5,000
Ni	Ionic	2	500	200	200	100	—
Mo	Ionic-Particulate	10	10	100	—	20	—
V	?	1	1,000	100	—	20	—
Ti	?	1	1,000	1,000	—	40	—
Cr	?	0.05	300	—	—	—	—
P	Ionic	70	10,000	10,000	10,000	40,000	2,000,000
S	Ionic	900,000	10	5	1	2	—
I	Ionic	50	10,000	100	50	10	—

Modified slightly from Krumholz, Goldberg, and Boroughs 1957.

- Organisms at the second trophic level (e.g., zooplankton) tend to concentrate radionuclides that are in particulate form.
- There are large species differences and even large differences between individuals of the same species. These are largely unexplained.
- Uptake is, in general, more rapid and in larger amount in growing organisms and populations.
- There is no simple rule that can be generally applied regarding the transfer of radioactivity up the trophic structure. It all depends on who feeds on what.
- Retention is essentially indefinite in the calcified portions of organisms in the sea but may be very short in soft tissues.
- Many radionuclides partition into soluble and insoluble fractions.
- The chemistry of seawater is complex. While the buffering capacity is much greater than in freshwater systems, and this lends some stability to entities such as dissociation constants of compounds, there is no substitute for measurements instead of calculations. For example, Feldman (1976), at the University of Rochester, pointed out that equilibrium calculations are probably not valid for submicroconcentrations of radionuclides in seawater. He predicted and showed examples of the existence of radiocolloids in seawater. This may help explain some apparent anomalies.
- Despite what appear to be large concentration factors in organisms, the bulk of the radioactivity in seawater is in the nonliving phases. However, continual turnover by organisms and rapid repopulation can accomplish considerable transfer from water to biomass to deep layers of the ocean or the sea floor. Polikarpov (1966) shows how plankton organisms with a

concentration factor of 1,000 can accomplish transfer of radioactivity downward at ten times the rate of hydrological transfer. This was with a mixing coefficient of 0.1.

10. As in the freshwater systems already discussed, a significant portion of the activity in marine systems finds its way eventually to the bottom sediments.
11. As a crude generalization, it can be said that cesium, strontium, and zinc tend to exist in ionic forms in the sea, while ruthenium, cerium, zirconium, yttrium, niobium, and iron tend more to exist as colloids or suspended particles (Whicker and Schultz 1982).
12. Chemically analogous elements such as potassium and calcium in seawater may act as carriers for elements such as cesium and strontium.
13. The activation products and those fission products that tend toward colloid formation are, in general, of more biomedical concern than elements like strontium and cesium, in contrast to the terrestrial environment.
14. Marine systems handle the same spectrum of radionuclides quite differently from freshwater and terrestrial systems. A first contrast is due partly to the presence of much larger quantities of potential analogues in seawater. A second contrast resides partly in the much greater mixing in the aqueous as compared to the terrestrial environment.

The dramatis personae in all of this have already been named in part. We will meet others as we progress.

B. Effects of Radionuclides on Ecosystems

The first approaches to determining biological effects of ionizing radiation in ecosystems were directed toward individual organisms. As described in section II, the pioneering work was done at the University of Washington Applied Fisheries Laboratory during World War II. It began with x-irradiation of salmon and trout at various stages of development and gradually expanded to other aquatic organisms.

Donaldson and Foster (1957)^(a) give a succinct review. Algae and protozoa required extremely high doses (many thousands of roentgen units) to show lethal effects. Mollusks and crustaceans were somewhat more sensitive, requiring doses of a few thousand roentgens for 50% lethality. Fish were the most sensitive with an LD₅₀ on the order of 1,000 roentgens. *All* of these are higher than the LD₅₀ doses for higher vertebrates, including that calculated for humans.

Donaldson and Foster review also the radiosensitivity of different life stages of various aquatic organisms and report the usual greater sensitivity of gametes, eggs, and other rapidly developing stages. Qualitatively the effects were like those seen in "higher" organisms, although the time course was generally longer, presumably because of the lower temperatures. Genetic effects were seen also, but it appeared that the genetic apparatus of many of the aquatic organisms studied was relatively radioresistant compared to the cells of terrestrial vertebrates.

Immediately post-World War II, several field experiments were set up using large radiation sources. These were studies of terrestrial organisms. They have already been described briefly (Brookhaven; Oak Ridge; Dawsonville, Georgia,

(a) Details appeared in the University of Washington Applied Fisheries Laboratory reports cited by Hines (1962).

i.e., Emory University; Puerto Rico). All of them involved large radiation sources with rapid diminution of the intensity with distance from the source. They were primarily useful for determining relative sensitivity of trees and plants. Animal populations were too mobile, and their dose could not be determined. A special radiation field was set up at the NTS by N. R. French and associates from UCLA (French 1964, 1965, 1969, and undated) to provide both a relatively low-level chronic irradiation pattern and a tight enclosure to prevent immigration and emigration of the animal population (lizards and small rodents).

There were some surprises from these large field studies, e.g., the unexpectedly high radiosensitivity of the conifers. Since this work was all with external radiation sources, space prohibits further exposition here.

By contrast, effects work concerning radionuclides in ecosystems, either terrestrial or aquatic, has not produced as much information, nor could it be expected to. This is largely because massive contamination would be needed to produce doses comparable to those delivered by the large sources of gamma rays and neutrons. Instead, the search for effects from radioisotopes in natural ecosystems has had to rely on the doses delivered by whatever contaminating events have taken place. Even though the total amounts of radionuclides from fallout and other sources may have been large, the dilution factors have been very large also. Thus, the doses are not high except locally (chapter 12). Partly because of this difference in magnitude of the dose, and partly because of the tremendous resiliency of the ecosystems at low to moderate levels of perturbation, few clear bioeffects have been seen from radionuclide contamination except around highly contaminated local foci.^(a) The effects (or lack of effects) of radiation from radioactive wastes seen in the organisms of the dry bed of White Oak Lake at Oak Ridge, in the Clinch River, the Columbia River and its estuary, and the Animas River have already been described briefly. Effects of plutonium and tritium have been studied at the NTS. They have been minimal, as we will see in chapters 12 and 14.

Nevertheless, the story was not a monotonous litany of negative findings. Polikarpov (1966) ran through most of the literature from the USSR, eastern and western Europe, and North America on the effects of single and chronic doses of external radiation on a variety of aquatic organisms. This includes work with ova, larvae, etc., and is nicely summarized in the useful tables in his important book. For the chronic doses, he included effects of ^{89}Sr , ^{90}Sr , and ^{90}Y , mixed fission products in rainwater, etc. He looked at populations of periphyton to determine which forms dominated as a function of time and dose. On the basis of preliminary data, he predicted that incorporated radionuclides would be more effective on forms such as larvae or fry than a comparable dose from an external radiation source.^(b) He concluded that, despite problems with incomplete experiments and of extrapolating from laboratory to ecosystem, *no further radioactive contamination of seawater is admissible*, at least until marine radioecology has a chance to check out phenomena such as those he describes. Unfortunately, this author can find little evidence of a careful and formal

(a) We are discussing ecosystems or major components thereof, not the occasional effect of a high dose on individuals as at Enewetak.

(b) Polikarpov quotes work showing abnormalities in the larvae of the sea fishes at concentrations of ^{90}Sr , ^{90}Y as low as 10^{-10} to 10^{-12} Ci/l (10^{-5} to 10^{-6} pCi/l), and notes that these levels had already been reached at the Pacific Proving Grounds and in the Irish Sea.

follow-up of these findings in subsequent years in the same or in other systems. The observations seem to stand more or less alone.

The most difficult problem is, of course, the complex ecosystem itself. In interviewing many of the outstanding figures in radioecology for this book, the author has asked if they knew of or had any reason to suspect that there might be some exquisitely sensitive organism or process in some major ecological system whose disabling would have far-reaching effects (Donaldson 1979; Foster 1979; Seymour 1979; Auerbach 1979; Larson, Welander, and Bonham 1979; and others). They all answered in the negative. The ecosystem is too resilient for that. However, there are ways in which a subtle change could become a significant one.

In this connection, the book by Whicker and Schultz contains some revealing paragraphs. For example:

... An ultimate objective of radiation ecologists was to investigate the effects of ionizing radiation at higher levels of integration, efforts were made to irradiate populations, communities, and ecosystems in place.

The complexities associated with such investigations are formidable. A considerably greater degree of complexity is involved when one considers the effects of ionizing radiation (or any other stress) at the population or community levels as compared to the organism level, particularly when investigations are conducted in the field. At the community level, direct effects of radiation on individuals become intertwined with indirect effects of multiple interactions and secondary effects. In a natural community, niche space is available to populations only under the condition that their existence within a certain space and at a certain density is compatible with conditions imposed by the abiotic environment and by other members of the living community. Regulation of a plant or animal population is achieved by relationships of space, nutrient supply, available sunlight, water, and a host of other factors, all of which are affected by other populations of the biotic community. The result then is that changes observed in a community following irradiation are caused not only by ionizing radiation per se, but also by interactions and secondary effects which result from the inherent nature of that community and its supportive elements. Without ancillary information, the relative importance of factors responsible for observed changes in an irradiated community may be obscure. These complexities and resulting high costs of experimentation have restricted the number and magnitude of field investigations. (Whicker and Schultz 1982, Vol. 2, p. 119)

These questions were examined in some detail by John Strand, Dale Becker, and Paul Fujihara at Pacific Northwest Laboratory, and their deliberations resulted in a brilliant monographic publication in 1978, on columnaris disease in Columbia River fish (Becker and Fujihara 1978). The publication was, in fact, only the second monograph published by the American Fisheries Society in its 115-yr history. By the end of the 1950s, the Columbia River adjacent to the Hanford site had been considered the source of induction of high-virulence strains of the bacterial pathogen, *Flexobacter columnaris* and the source of their widespread dissemination among resident salmon species. Reactor-warmed water, as an enhancing agent for many bacterial diseases in fish, and radiation, as a potential mutagen, were seen as a complex of factors that might explain the rather catastrophic outbreaks of this disease. In this monographic study, various environmental influences on epizootic outbreaks were evaluated systematically, including temperature, fish confinement, reservoir host populations, water quality factors, injury, and radiation. The factors were studied singly and in combination, in fish and in the bacterium. In the final analysis, the disease proved to result from a complex interaction between the host, the pathogen,

and the environment. A steady displacement of the coarsefish vector (carrier) population to the Hanford reach of the Columbia River, and a change of virulence in the unaffected carrier, aggravated by temperature elevation and crowding in fish ladders at the new dams, were shown to act in concert to cause these devastating outbreaks of columnaris disease in salmon. In the years following shutdown of the Hanford production reactors, the disease outbreaks continued until operation of the Columbia River dams was eventually modified. Radiation as a causative factor was ineffective in either the bacterium or the fish except at cumulative doses far above any possible exposure to the reactor effluents. A corollary of these studies was the experimental demonstration by Dr. John A. Strand^(a) and colleagues (1977) of tritium suppression of the primary immune response in rainbow trout. How this effect on the fish immune system was differentiated from the effects of the columnaris pathogen is an interesting story (Strand et al. 1982).

Fish populations in the Columbia River ecosystem are besieged by many adversities. Quantifying the relative importance of a single factor in a complex of interwoven factors, all influencing fish populations, is a formidable task, about which more is said in section IV F (Tritium in the Environment).^(b)

In a paper by Templeton and a panel discussion at the Rochester Conference on Environmental Toxicity of Aquatic Radionuclides, some additional generalizations can be approached (Templeton 1976, Miller and Stannard 1976). The abstract of Templeton's paper is given below.

There is some concern that with the expansion of nuclear energy for power the oceans will be subjected to an increasing radiation dose commitment as a result of effluent discharges. This chapter discusses some implications of the present dose commitment and attempts to evaluate the potential effects upon aquatic populations. Experimental studies have indicated the sensitivity of some stages of individual organisms to irradiation, however the dose rates required are many times above that presently existing, even at major waste disposal sites. From a consideration of the role of natural regulatory mechanisms in exploited populations, it would appear that populations of highly fecund species are unlikely to be perturbed by present levels of radiation from controlled disposal to the marine environment. However, for species of low fecundity, additional stress, whether from fishing, irradiation or other pollutants, may decrease their chances of survival. Consideration of potential genetic effects is limited by a lack of quantitative data on radiation-induced genetic changes in aquatic populations. Some limited generalizations are made indirectly from experimental data on other organisms. (Templeton 1976)

The IAEA in Vienna prepared one of its technical report series on the subject of effects of ionizing radiation on aquatic organisms (IAEA 1976b). Its general conclusions are comparable to those of Templeton just quoted. This volume is a concise and handy summary of the field.

The panel discussion at Rochester included remarks by Edward Goldberg to the effect that we have been looking for biological effects of agents such as marine pollutants, e.g., halogenated hydrocarbons, heavy metals, and artificial radionuclides for about twenty-five years and have drawn essentially a blank. Should mega-fish experiments be mounted comparable to the famous mega-mouse genetic experiment at Oak Ridge? There were many at the conference

(a) Dr. Strand is now the manager of the Marine Research Laboratory at Sequim, Washington.

(b) Parts of this and the previous paragraph were supplied by Dr. Vaughan.

who thought we could not learn in any other way, but there were others who were convinced that these populations are all relatively radioresistant, and we would do better to put the effort into studying effects of chemical pollutants to which they may be more sensitive. In fact, the idea was expressed (by Dr. George Berg) that even on conclusion of a large experiment with radioactivity the results might point at some agent far away from radiation or radioactivity as the culprit.

A suggestion made by Richard Foster was to mount studies halfway between the laboratory and the uncontrolled environmental situation. This would involve small lakes, large terrestrial compounds, etc., some of which have already been alluded to. These would be expensive experiments, and much planning would be needed. Only the future will tell if we have the zeal to fund them.

Meanwhile, we must be content with the knowledge that careful investigation has shown it is possible to perturb the environment with radioactivity at high doses, but that effects are not demonstrable at the average doses found in today's environments. Yet, while research on an international scale has been brought to bear on this problem, and the results in "unusual" organisms do not seem greatly at variance with those from the more commonly studied higher vertebrates, we have in no way covered all possibilities. The breeding grounds and habitats, both terrestrial and aquatic, for large sectors of the biosphere cannot be said to have been really thoroughly studied for sensitivity to either radionuclides or chemical toxins. Meanwhile pollution is mounting, some of it in crucial spots.

A suitable summary for this section on effects in ecosystems is one prepared by Whicker and Schultz regarding the effects of chronic irradiation on populations:

Concerning plant communities, stands characteristic of harsh environments and climatic extremes are relatively radioresistant and early seral stage communities tend to be more resistant than following successional stages. Radiosensitivity of plants is related to characteristics of chromosomes and cell populations and to stature and growth form, with the smaller herbaceous plants being more radioresistant than larger, woody species. Vascular species are much more sensitive than thallophytes. Reproduction and productivity may be reduced at reasonably low exposures. At higher exposures, breakdown of community structure can be expected. Alteration of plant community is related to radiation dose rate, time of exposures, radiosensitivity of component populations and to secondary effects and interactions.

With respect to performance of terrestrial animal populations, the process most susceptible to impairment by radiation stress is reproduction. However, some populations that exhibit rapid repopulation potential can often adjust to reduced natality and still maintain stable numbers. On the other hand, longer-lived species with normally low reproductive potential can gradually decline in density to the point of extinction at relatively low chronic exposure rates. Across the animal kingdom, there is a 2 to 3 order-of-magnitude range in innate sensitivity to radiation. Furthermore, the biotic and abiotic environment, as well as many other innate characteristics can significantly alter the response of animal populations to radiation. As a result, the prediction of population response in irradiated ecosystems becomes a very difficult task, unless the exposures are either very low, or very high.

Studies on natural aquatic populations have been limited to systems that have been contaminated with radionuclides to produce dose rates generally less than 1 rad/day. At such levels, the responses of aquatic populations have been very difficult to document and quantify. While genetic mutations have been observed at the chromosome level in organisms subject to such dose levels, the effects on

fecund populations subject to strong selective pressures appear inconsequential. Based on laboratory investigations, developing embryos of fish can be expected to be one of the most sensitive components of aquatic systems to radiation, but there is considerable variation between species, as well as within species, depending on stage of development and environmental factors. (Whicker and Schultz, 1982, Vol 2, pp. 165-166)

It is very likely that other perturbations of the environment deserve a higher priority now than radioactivity. Nevertheless, we can be glad that the attitude of caution developed in the very earliest days has persisted regarding radioactivity, and the ecological community is alert for the presence of any "sleepers."

C. More About Nuclear Power Reactors

We have already reviewed the first major nuclear reactor accident, Windscale, as part of the historical review of the early years. We will consider here some more generic matters and one other specific incident, Three Mile Island. The participants in this work are ubiquitous.

Even though it is clear that mining of uranium ores and fuel reprocessing plants contribute much higher activity levels in *routine* operations than a power reactor, it is the reactor that engenders the most apprehension because of its potential, however remote, for release of very large quantities of radionuclides in a major accident. To evaluate these potentials, much of the biomedical research already discussed in this book had to be brought to bear. Added to that were the special problems of environmental distribution (see for example, Reinig 1970).

Obviously, any biomedical data relating to routine releases from reactors to the environment fall either into the category of computation of doses from measured activity of effluents or of epidemiologic surveys. For calculation of doses to humans, much use has had to be made of the critical pathway and the critical population (critical group) concepts. Probably the most succinct and overt early discussion came from Committee 4 of the ICRP in its Publication 7 (ICRP 1965). It is taken up in detail in chapter 15. It is convenient to choose one or two of the numerous and complex pathways, viz., one(s) that would involve the highest collective dose, or sometimes the highest individual dose, and designate the population involved as the critical population. This may be, for example, a specific occupational group like fishermen or the residents of a particular area with food and/or water from the critical pathway. Then the radionuclide or radionuclides that both pass through that pathway in largest amount and enter the human body most readily can be selected as the critical nuclide(s).

Experience has shown that detailed study of all potential pathways and all potentially critical nuclides is seldom needed. For example, the strontium-plant-cow-milk-child pathway easily takes precedence over others under many conditions. A general diagram of possible critical pathways is given in ICRP 1965.

Once the associated radiation dose has been calculated, the potential risk can be estimated and discharge rates regulated to well below permissible levels. Extrapolations from the research data to operational matters have produced a voluminous literature based almost entirely on computations. The early outlines can be seen in the referenced ICRP publication, while more recent features appear in the numerous Regulatory Guides of the U.S. NRC and predecessor documents under the AEC.

Biomedical research on possible *effects* of routine discharges from nuclear power plants consist primarily of epidemiologic surveys. Many, such as the

Mancuso study of Hanford, concern the combined effects of many sources. Many others are still in progress and will require many years for completion. Still others are still at the feasibility-study stage.

Quite early, Ernest Sternglass, University of Pittsburgh, declared that he had convincing evidence of increased infant mortality around the sites of operating nuclear power reactors. He had already alleged similar effects in cities receiving more than the average amount of fallout from the weapons tests at the NTS. No waiting for a feasibility study here! Since his saga begins with fallout problems and was translocated, essentially intact, to reactor sites, we will discuss both aspects together in chapter 12.

Claims of a similar nature have been made concerning the population living near the Indian Point, New York, nuclear station. Weik (1969) cited at Joint Committee on Atomic Energy (JCAE) hearings increased cancer incidence in the population—unfortunately much too small for either statistical or epidemiologic suitability. Fadeley Cunningham (1965) presented data showing increased malignancy incidence for populations in certain counties of Oregon near the Columbia River and attributed the increase to radionuclides from the Hanford reactors. The flaws in this study were discussed by Stannard (1973b, p. 349).^(a) There have been and will be other such correlations that we will have to leave to the epidemiologists to interpret. Getting an epidemiologically suitable sample is not easy, as we have seen in this book from the radium chapter on.

At the Third Congress of the International Radiation Protection Association there was a series of summaries of radiation doses from various sources, such as natural radiation, medical uses, accidents, and routine operations.

So much for the routine operations. The evaluation of radiation doses and health consequences of a serious accident at a nuclear power reactor has also been almost entirely computational. Only the special field tests, to be described in chapter 14, involved actual measurements "before the fact." All others have been computational or, "after the fact," like Windscale, the Monroe Reactor, Three Mile Island, and others. We will review briefly the gradual development of appreciation for what could be involved in a major reactor accident.

An early review concerned radiation from the passage of a hypothetical cloud of reactor debris (Holland 1956) and came from the U.S. Weather Bureau. Such evaluations of dose from cloud passage have continued under the general title "submersion dose" and appear in the latest ICRP report on radionuclide standards (ICRP 1979). Walter Snyder and his associates at Oak Ridge should be credited with keeping such calculations current and meaningful over many years.

Early analyses of aspects broader than cloud passage alone were made by Parker and Healy at Hanford (1956) and by Marley and Fry from the United Kingdom (1956). These were condensed papers given at the first Atoms for Peace Conference and reflected work that appeared earlier in in-house documents. A still earlier report in terms of publication date came from the Knolls Atomic Power Laboratory in 1954 (Fitzgerald, Hurwitz, and Tanks 1954), but it did not receive as wide distribution.

Probably the first report on large accidental releases to receive widespread general attention in the United States was one prepared by staff at BNL, first as a

(a) For example, certain pertinent counties away from the river were omitted without explanation, age-sex adjustments were inadequate, etc.

laboratory report (BNL 1957), and later published in part in the proceedings of the second Atoms for Peace Conference (Kuper and Cowan 1959). They considered two types of postulated events: release of a fraction of the fission product inventory from a 500-MW (thermal) reactor that had operated for 180 days, and a core meltdown in which the fuel and all of the volatile fission products were released.

At the same international meeting, B. P. Leonard (1959) from Convair presented estimates of the amounts of radioactivity, possible doses, and probable number of people affected in rural and urban environments for either "run-away" or "meltdown" incidents. He took pains to review the influence of meteorological variables and other perturbations and showed that they could make fairly large differences in the outcome.

In both papers, the calculated consequences of the types of accident were catastrophic and created something of an uproar.^(a)

Since these early reports, there has been a constant drumbeat. No one disputes the potential biological effects of the release of any substantial portion of the inventory from a large power reactor. Many laboratories and individuals have devised criteria for the siting of power reactors. For example, an important midyear topical symposium of the Health Physics Society was devoted to nuclear facility siting (Voillequé and Baldwin 1970). Here discussions ran from consideration of building a power plant deep in rock in the city of Stockholm, Sweden, to the idea of never locating a nuclear power plant less than many, many miles from a populated area.

In the next few years, the AEC sponsored and produced more or less continuous studies of possible population doses and design-objective guides not only for reactors, but for the entire nuclear industry. The EPA did likewise for the environmental implications. Most of these entailed estimates of the growth of nuclear power that we now recognize as overestimates. Yet the data and conclusions give a good picture of the activities and thinking of the period.

The reports include WASH-1209 (AEC 1973c) and an earlier preliminary version, WASH-1139 (AEC 1972). This was followed by WASH-1250, a report specifically on the safety of nuclear power reactors and related facilities (AEC 1973d). Each of these focused on the year 2000, and the series has become known as "The Year-2000 Study." The content can be estimated from the titles as given in the bibliography to this chapter.

The EPA's contributions began as an estimate of ionizing radiation doses in the United States in the period 1960-2000 (Klement et al. 1972). This was followed by specific limits for environmental contamination with radionuclides (see chapter 15 for more details).

At this same time, the idea of keeping all exposures "As Low as Reasonably Achievable" (ALARA) came into its own and was blessed by incorporation into a final environmental statement, WASH-1258 (AEC 1973b). Also, Appendix I of the code of Federal Regulations was modified because of environmental pathway findings (chapter 15). A concise summary of the events of this approximately five-year period was produced by Hart (1974).

An even more extensive reanalysis came in 1975 in the Reactor Safety Study, WASH-1400 (AEC 1975), the so-called Rasmussen Report. This multivolume

(a) It is reported that AEC later tried to hush up these worst-case conclusions since the chance of releasing all of the fission products, even in a meltdown, is exceedingly small. Might as well try to hush up a tornado!

document contains much biomedical information, considerably more than some of the earlier reports. Yet, primarily it fine-tunes the implications drawn earlier. The most significant advances were better risk estimates, better evaluation of environmental parameters, and much more information on the actinide elements. We need still more on these. It is clear from this report, however, that the chief problems are engineering ones, i.e., the probabilities that various levels of events could occur. The report is very strong on these, using a "fault-tree" analysis.

The accident at the Three Mile Island nuclear power plant near Harrisburg, Pennsylvania, needs no description here. Fortunately, the environmental radiation levels were never high enough to test any of the calculations referred to above. The collective radiation dose to the population out to fifty miles was estimated at 2,000 person-rem.^(a) Estimated annual collective dose to the same population from natural background radiation was about 240,000 person-rem in the same period. This was true despite the high levels of contamination within the facility.

An interesting environmental measure of possible contamination from the Three Mile Island plant involved measurements of ^{131}I in meadow voles (Field et al. 1981). Thyroids from these animals contained more ^{131}I than normal, and the amount varied among the three sites chosen. The highest (11.4 pCi/thyroid peak, 5.6 pCi/thyroid average) was at site III, the one predicted to show the highest concentrations by the DOE. None of these were alarming, but the work resulted in the vole being proposed as a monitoring organism for ^{131}I contamination of ecosystems.

Some very real biomedical effects took place, but they were not radiation effects. As stated by Fabrikant (1981), (director of the Public Health and Safety Task Force of the President's Commission on the Accident at Three Mile Island, now domiciled at the Donner Laboratory in Berkeley and the Department of Radiology at the University of California, San Francisco), there were real effects on the mental health of the people living in the region and the workers at the plant. These patterns of anxiety, confusion, and sometimes paranoia showed a relation to distance somewhat like a conventional dose-response pattern.

It should be clear that biomedical research has developed ample information to assay and predict the effects of large accidental releases from nuclear power reactors. The effects of routine releases still remain with the problems of the low-dose realm. The engineering problems and the true probabilities of accident-causing defects remain in much need of further diligent investigation.

D. The Liquid Metal Fast Breeder Reactor Program

In the early 1970s, there were indications that the world's supply of uranium might be insufficient to meet the expected demands for electricity from nuclear power. The idea of a breeder reactor, under discussion for a considerable period, received additional impetus at this time. For various technical reasons,

(a) There are those who point out that this average figure is not meaningful. The maximum individual dose could have been higher. This cannot be denied. The measurement resources were too strained and the circumstances too hectic. Would that they had enlisted the cooperation of the population as the British did at Windscale to get more individual and early measurements.

cooling by liquid sodium was preferred over cooling by water or air, and a cycle that bred mostly plutonium was favored. However, the possible amounts of plutonium and of other transuranics formed were enormous. Add to this the chemical and explosion hazards of liquid sodium at high temperature, the need for extremely careful planning and analysis of such an installation became quite apparent.

About mid-1973, a massive environmental impact statement (EIS) (see later section and chapter 16) was undertaken, which involved every aspect of the transuranics. It brought in every laboratory with expertise in the field. All of the toxicological research on plutonium and other transuranic elements we have reviewed in earlier chapters was brought together, including yet another analysis of the "hot particle" problem in lung. Hearings were held with many volumes of testimony; some of it directed at the entire uranium fuel cycle. The monumental EIS for the Liquid Metal Fast Breeder Reactor (LMFBR), WASH-1535 (AEC 1974), contains almost all anyone could want to know about what had been done about transuranics and their hazards. The big gap concerned their behavior in the environment. This was partly because most of the information had been obtained from desert environments, like the NTS, or very specialized environments like the Pacific Proving Grounds.^(a) Since the site chosen for the LMFBR was on the Clinch River near Oak Ridge, Tennessee, the lack of ecological information on transuranics applicable to a humid forested environment was apparent.

The AEC gathered an environmental team to develop a research program to fill in the gaps and to further expand our knowledge of the cycling of transuranic elements in all environments. This involved HASL in New York, the environmental group from the NTS, including the Nevada Applied Ecology group whose work we will review in chapter 14, the Lawrence Livermore Laboratory, PNL (Hanford), the University of Washington fisheries group, the UCLA Atomic Energy Project, and the Woods Hole Oceanographic Institution. The areas of immediate concern are as outlined in figure 11.13, taken from the foreword written by R. L. Watters (1980) to the recent volume prepared for DOE, *Transuranic Elements in the Environment* (Hanson 1980).

The listing is, of course, comprehensive for the short term. There was already considerable information on some of the topics, as a perusal of recent symposia, such as the one held by the IAEA in San Francisco (IAEA 1976a), testifies. It even included a modicum of work in humid environments such as that at the Savannah River Plant. However, there were special concerns for the longer term as described by Watters below:

The areas of research just mentioned are of immediate concern, but beyond these near-term considerations are those related to the possible long-term persistence of the transuranic elements in available form on the scale of hundreds and thousands of years. Such considerations are very difficult to address adequately with contemporary research. However, two approaches are under way which may provide reasonable first approximations to the prediction of long-term behavior. One is the theoretical approach to studying the chemical and physical processes in soil of those radionuclides with the objective of developing good thermodynamic data. We need information on the equilibrium concentrations of the various oxidation states in different environments, on complexation processes, and on diffusion

(a) A few others such as Palomares, Spain, and Thule, Greenland, were involved also (chapter 14).

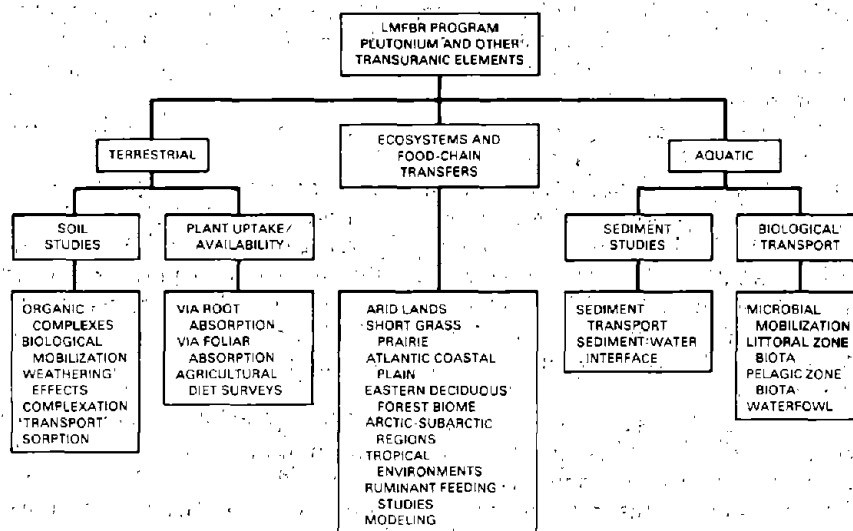

FIGURE 11.13. United States Department of Energy, Office of Health and Environmental Research, transuranium elements research program. (Redrawn from Watters et al. 1980.)

coefficients for various species. We can then apply this type of information to predictive modeling. An empirical approach would be to study the distribution and environmental behavior of naturally occurring elements that have properties analogous to those of the transuranium elements. For instance, the availability for plant uptake of the rare earth neodymium, which has been subjected to weathering for thousands of years, may provide a basis for predicting the uptake of americium after long periods of time because americium and neodymium have quite similar chemical and physical properties. Other rare earths, uranium, and thorium are also candidates as analogs for some of the transuranic elements in environmental studies. (Watters 1980)

A further indication of the extent of the effort engendered by the potential for an LMFBR is the fact that workshops involving all aspects were held in Estes Park, Colorado, in July 1974 and in Seattle in November 1975. Hanson (1980, p. vii) states that environmental aspects of research on transuranic elements expanded sixfold between these two meetings. Incidentally, the second workshop was the basis not only for the book edited by Hanson, but the grand review of all of actinide biology in 1977 discussed in chapter 8. There was a third workshop in April 1977 held at Woods Hole, Massachusetts. It did not produce the same enthusiasm as the first and second.

Since the Hanson volume is something of a landmark, its table of contents is reproduced at the end of this chapter (note 4).

As is well known, the LMFBR has not been built. It may never be built. Despite the reassurances regarding potential health effects, the idea of a plutonium economy with problems far wider than potential biomedical ones has engendered extreme caution. Nevertheless, the environmental aspects were so very thoroughly analyzed on paper that a short summary appears worthwhile.

This is given below based in part on a clear and concise summary prepared by N.F. Barr of ERDA (Barr 1976) for the IAEA symposium already cited. These give a clear idea of the wide range of disciplines and expertise that had to be brought to bear.

First, the potential amounts of transuranic elements that might be released, i.e., the "Source Term," had to be estimated. This had to be put in terms of the electrical energy produced, since no one knew how many megawatts or gigawatts might be produced. The dominant source for routine operations was expected to be releases from the fuel reprocessing plants, not the LMFBR itself. This was estimated at 1 mCi of alpha-emitting transuranics per 1,000 MWe/yr with all other sources at factors of ten or more lower. The composition of the releases was based on the composition of high burn-up fuel and was assumed to exist as small airborne particles with an activity median diameter (chapter 9) of $0.3 \mu\text{m}$.

This release rate was estimated to be one part in 10^9 of the materials present. In other words, it assumed containment was good to one part in a billion, stated to be an already accomplished fact technologically.^(a)

The next step was estimation of what fraction of the released material would find its way into humans. For *direct* inhalation, an assumed particle size distribution of the inhaled fraction was taken as 5×10^{-6} . This figure was based on model meteorological conditions for the north central part of the United States. It is that portion that would be inhaled *before* the material reached the ground. In addition to this, wind would pick up some of the material after deposition on the ground and resuspend it. This is represented by a resuspension factor (chapter 15) and is larger initially than it is later on, since the material tends to become fixed with time, be carried to less superficial portions of the soil, etc. The initial resuspension factor was taken as 10^{-5} , with decrease to a constant minimum value of 10^{-9} on a half-life of fifty days. Combining this postdeposition pickup with the amount initially inhaled resulted in an estimate that about 10^{-5} of any amount of transuranic released would reach humans by the inhalation route if exposure were indefinitely long.

The ingestion pathway of most import, based upon laboratory and field studies, was taken as plant material. It was assumed that the released transuranics were uniformly distributed on the soil surface and that the plant material reached a concentration of one-tenth of that in the soil. The fraction absorbed from the gastrointestinal tract was taken as 0.3×10^{-5} for plutonium and 10^{-3} for americium and curium, following ICRP figures. It was calculated that the ingestion pathway made a negligible contribution immediately after release but that it could reach 10^{-2} of the amount released eventually (i.e., over the rest of time).^(b)

The next step was calculation of radiation dose equivalents. These used the techniques described in chapter 20 and throughout the literature. For

- (a) This was for routine operations. There was more uncertainty regarding contributions of "off-normal" operations. It was expected these could be checked out when the facilities were designed, built, and operated. This very uncertainty may have contributed to the reluctance to proceed with the program.
- (b) Because of the indications that plutonium and other transuranics may become more transportable with time in the environment, a contributing factor from ingestion of as high as 10^{-1} of the amount deposited was indicated by Barr (1976) as being used. However, this was not clearly revealed in the EIS.

inhalation, the integrated seventy-year dose equivalent was approximately 1 mrem/pCi (10^{-12} Ci) of transuranic inhaled. Combined with similar dose equivalent calculations for ingestion, an estimate was made of potential health effects. This was couched in terms of the risk of developing cancer (pulmonary, skeletal, or liver) and of genetic defects. The risk estimates came from the NAS-NRC (BEIR) reports and the United Nations (UNSCEAR) documents (chapter 16). Most of the total risks were in the realm of 0 to 10^{-4} to 10^{-3} probability per 1,000 MWe year. (Total probability of cancer ran from a minimum of 0 to a maximum of $380 [138-1,045] \times 10^{-6}$ and that of genetic defects at genetic equilibrium from a minimum of 24×10^{-6} to a maximum of 600×10^{-6} .)

The above is a very incomplete description of the monumental discourses and detailed calculations that went into evaluation of the LMFBR. It is probably the largest compilation of its kind ever undertaken. It is reviewed here for its intrinsic interest and to show the extent to which prospective planning can be brought to bear on the health aspects of a major enterprise. It is ironic that all of this concerns a facility that has not yet been built and may never be built. Thus, the validity of many of the engineering assumptions may never be tested. The validity of the biomedical data is being tested constantly by the ongoing research programs in the radionuclide field. Of these, obviously, some of the environmental parameters are the most uncertain. Unfortunately, and despite the very sizeable inflow of new information, there is now little motivation for investigators or administrators to return to the LMFBR modeling and correct or modify it on the basis of new results. We will have to obtain that information by other means.

As would be expected with so complex an enterprise, there are dozens of parameters that had to be based on insufficient or poor evidence. Sometimes the figures chosen may have overestimated the eventual risk. Indeed, there was a tendency to choose the more conservative alternatives. Yet, there were many figures that had to be largely guesses and may have been underestimates.

Naturally, there were many critics ready to challenge each assumption. Since the overall risk estimates were close to what is gradually becoming the neighborhood of acceptable overall risks, any major changes in the LMFBR model parameters could move the estimated risk into an unacceptable realm. Perhaps the most frequently challenged figures were related to engineering, e.g., the true ability to maintain a containment factor of 10^{-9} . Yet, the biomedical parameters came in for their share of challenges too.

This tremendous effort did two things, at least, for the biomedical research with transuranics: (1) it brought together a large portion of the published and unpublished literature in the field; and (2) it made apparent that, despite our progress, the story is far from complete, and research, both field and laboratory, cannot be relaxed.^(a)

(a) Alternative technologies were, of course, under consideration. Some had what appeared to be considerably reduced biomedical implications. One of these was the high temperature gas cooled reactor (HTGR), which could be made into a breeder. Till (1976) gives a lucid description of the two fuel cycles involved, ^{235}U HTGR fuel and LMFBR fuel, and compares their potential toxicity on recycling. Many steps, such as toxicity of the fuel itself, as well as radiological insult to aquatic plants, invertebrates, fish, and terrestrial animals dependent on aquatic food supplies showed from some to considerable factors favoring HTGR fuel. Nevertheless, Till concludes that, once

It is unfortunate that this major compendium is not likely to be easily available in future years, since such documents have a tendency to go into limbo when the project is completed or found to be impractical.

E. Transuranics in the Environment

The above discussion of the LMFBR leads to a brief general discussion of transuranic elements in the environment. All four of the chapters on radionuclides and the environment consider work with the transuranic elements such as plutonium, americium, curium, etc. in many contexts. Other chapters have addressed their biological effects in individual organisms.

It all started, of course, with the initial studies centered around the Hanford plant. It continued with many special tests and events that we will discuss in chapter 14. The field began a general crescendo in numbers of laboratories and investigators in the early 1970s. The eleventh Hanford biology symposium held in September 1971 and entitled *The Biological Implications of the Transuranium Elements* had a series of presentations on environmental aspects (Thompson and Bair 1972). These included aquatic and terrestrial environments, plants, dairy foods, and critical environmental parameters in plutonium-safety evaluations.^(a) At about the same time, Rudolph, Carroll, and Davidson (1971) at Battelle Columbus Laboratories issued an annotated bibliography entitled *Plutonium and Its Effects in the Environment—A Selected Literature Survey*. This work covers much more than environmental studies. Indeed, most of the "effects" citations come from laboratory experiments.

In the same year, the Los Alamos Scientific Laboratory held an environmental plutonium symposium (Fowler, Henderson, and Milligan 1971). This included an excellent and much-quoted summary of the entire field by Wright Langham (Langham 1971); a discussion of the distribution of plutonium from accidents and field experiments by Harry Jordan (see chapter 14); consideration of methodology and analytical techniques by people from HASL; the EPA laboratories in Las Vegas and in Montgomery (Alabama), as well as Los Alamos, and industry; evaluation of airborne reconnaissance methods with a device known as the FIDLER (Field Instrument for Detection of Low Energy Radiation) (chapter 14);

released to terrestrial and aquatic environments, the two fuels apparently have about equal radiotoxicity. He urges further research to evaluate the potential radiobiological and ecological impact of the uranium fuel used for the HTGR. This author can find little evidence that this is being done. This may be because when the HTGR becomes a breeder it produces plutonium, and the differences between the potential input of the two fuels in the environment is further diminished. There is still the question of relative engineering safety of the HTGR, reputed to be greater than that of the LMFBR, but that is not an appropriate subject for this book.

- (a) The invited paper by Noshkin (from Woods Hole at that time) considers ecological aspects of the dissemination of plutonium and other transuranics in aquatic environments (Noshkin 1972). It gives a very complete summary table of ^{239}Pu concentrations and concentration factors in marine invertebrates and algae in various parts of the world, average concentration factors in several tissues of marine vertebrates, and the plutonium profile in bottom sediments. There are marked species differences. The paper by Romney and Davis from UCLA gives a similar review for ecological aspects of plutonium in terrestrial environments (Romney and Davis 1972). They remark on the relative paucity of information and describe the organization and objectives of the Nevada Applied Ecology Group (see chapter 14).

Detection of Low Energy Radiation) (chapter 14); plutonium in surface soil at Hanford; concentrations in some marine organisms; and air transport of plutonium at Rocky Flats. The symposium was closed by a review paper from Jack Healy on some of the problems of resuspension (chapters 14, 15).

Stannard (1973a) wrote a general review of plutonium in the environment as part of the large volume entitled *Uranium, Plutonium, Transplutonic Elements*, cited several times previously.

The American Nuclear Society organized a special session on "Environmental Levels of the Transuranium Elements" at its winter meeting in October 1974. The program for this is reproduced below:

Invited speakers for the "Environmental Levels of the Transuranium Elements" session at the American Nuclear Society Winter Meeting, Washington, D.C. October 30, 1974:

Chairman: Leon Leventhal, LFE Environmental Analysis Laboratories, Richmond, California 94804

1. "Quantitative Health Estimates of Transuranic Releases," Dr. Nathaniel Barr, DBER, US AEC, Washington, D.C.
2. "Toxicity of the Transuranium Elements with Special Emphasis on Plutonium," Dr. J. Newell Stannard, University of Rochester, School of Medicine, Rochester, New York
3. "Analytical Considerations Connected with the Transuranium Element," R. A. Wessman, K. D. Lee, W. J. Major, and L. Leventhal, LFE Environmental, Richmond, California
4. "Transuranics in the Marine Environment," Dr. Vaughan T. Bowen, Woods Hole Oceanographic Institute, Woods Hole, Massachusetts
5. "Transuranium Elements in the Atmosphere," C. W. Thomas and R. W. Perkins, Battelle, Pacific Northwest Laboratories, Richland, Washington
6. "Transuranium Elements on Land," Dr. J. H. Harley, US AEC, HASL, New York, New York
7. "Transuranium Nuclides in the Environment From Management of Solid Radioactive Waste," G. H. Daly and Anthony S. Kluk, DWMT, US AEC, Washington, D.C.

(HASL-29, April 1, 1975)

Each of the papers was a review and summary of how things stood in late 1974.

At about this time came the very large expansion of institutions and workers in the field engendered by the plans for an LMFBR as already described (section D 8). This spawned not only the large report described for the LMFBR, but a large IAEA symposium held in San Francisco in November 1975^(a) and numerous other special meetings on transuranics in the environment (not necessarily from LMFBR operations).

The IAEA symposium proceedings begin with an introductory address by James Liverman, the director of the Division of Biological and Environmental Research in ERDA, and are filled with individual reports on plutonium in aquatic and terrestrial environments in many parts of the world, biological uptake and transfer, pathways to humans, and environmental monitoring and evaluation.

At about this time, an independent summary on the international scene came from the Department of Radiation Physics at the University of Lund, Sweden. Elis Holm (1977) prepared a compact monograph whose primary purpose was

(a) IAEA 1976a.

discussion of the transuranics in the unique food chain characteristic of high northern latitudes: lichen-reindeer-man. We will consider this pathway further in chapters 12 and 15. However, it included a useful broad discussion of the sources of transuranics and their relations to other components of fallout. The monograph also takes up methodologies in some detail and reprints papers from the same group on plutonium in Mediterranean surface waters.

The Rochester International Conference on the Environmental Toxicity of Aquatic Radionuclides (Miller and Stannard 1976) also placed much emphasis on transuranics. Edward Goldberg from Scripps Institution of Oceanography proposed a global monitoring program for transuranics based on the use of two "sentinel" organisms, mussels and barnacles. W.O. Forster from the Division of Biomedical and Environmental Research of ERDA discussed the ERDA research programs, summarized source terms for transuranics, and discussed how to deal with various isotopes of plutonium, using the specific activity concept. J. N. Miettinen from Helsinki, Finland, described plutonium food chains with particular emphasis on the lichen-reindeer-man sequence and on an aquatic food-chain, sediment-benthic fauna-fish. Edgington and colleagues from Argonne National Laboratory described plutonium behavior in the Great Lakes, also with many data on food chains. (They found some very large concentration factors in plankton.) J. A. Hetherington from the U.K. Ministry of Agriculture, Fisheries and Food, whose work we met in connection with Windscale, described the behavior of plutonium nuclides in the Irish Sea. Livingston and Bowen from the Woods Hole Oceanographic Institution described behavior of americium in the marine environment and how it compares to plutonium. We have already mentioned the work on a pond ecosystem at Hanford described in that volume by Emery and Klopfer.

Finally, we have at hand for ready reference the book edited by Hanson (1980) and already quoted in earlier sections. An especially useful chapter for our present purposes is a "Synthesis of the Research Literature" by Watters et al. (1980). This contains tables and diagrams with referencing sufficient to provide a very succinct, yet complete, review of the field as it stood at the time of publication.^(a)

The primary thrust of the transuranic problems has, in recent years, gone more and more toward the problems of waste disposal. Much of the most pertinent work took place after the theoretical cutoff date for this book. However, something should be said about it.

The U.S. NAS-NRC has had a blue-ribbon committee working on waste disposal problems for many years. The Department of Energy and the EPA have devoted considerable attention and resources to the issues and possible technical solutions (DOE 1981; EPA 1981). This includes draft standards from the EPA. Of course, the NRC has formulated licensing and other requirements (NRC 1981). Very recently, the NCRP convened a task group of its committee on waste disposal (chaired by Merrill Eisenbud) to review criteria for the disposal of transuranium waste. A preliminary report from this task group (NCRP 1982) provides a handy review of the issues and makes recommendations somewhat contrary to those being developed by the regulators. For example, they state that radium in the environment behaves so differently from plutonium that establishment of

(a) Space precludes incorporation here of the very useful tabulations, but it is hoped the interested reader will have no difficulty in obtaining the publication, since it is recent and published by the DOE Technical Information Center.

a limit for transuranics based on analogy to radium is invalid. Further, they suggest that no single limit for waste concentration can be supported. Instead, site-specific pathway models should be employed using "thorough and comprehensive" studies of site-specific conditions.

We will close this section by quoting the summary from the synthesis by Watters et al. (1980) in the book by Hanson:^(a)

The preceding discussion leads to a number of generalizations that can be summarized as follows:

1. The nature of the source for release to the environment is important in the initial deposition and distribution of transuranic elements. However, as environmental factors, such as erosion, weathering, and biological processes proceed, the original chemical and physical properties are altered and source influence diminishes.
2. The major repositories of plutonium and americium are soils and sediments.
3. Suspended particles in air and water act as vectors for the physical movement of plutonium and americium, and erosional processes are the principal means of translational movement in the environment.
4. In spite of the large fraction of plutonium and americium residing in soils and sediments, chemical and biological processes produce a very small fraction of soluble species in terrestrial and aquatic environments. These species are incorporated in biological tissue, but the concentrations in biota have not produced demonstrable deleterious radiation effects.
5. An increase or decrease in the soluble fraction of plutonium over long weathering times cannot be demonstrated at this time. However, preliminary observations of naturally occurring analog elements indicate that plant uptake and transfer of plutonium and americium through food chains would not be expected to change appreciably over time.^(b)
6. Concentrations of plutonium do not increase from one trophic level to the next in natural food webs except for sorption by phytoplankton and one observation of starfish feeding on mussels.
7. The environmental chemistry of transuranic elements in marine and in oligotrophic freshwater systems is similar in a number of ways. However, significant differences in chemical species exist in many lakes where chemical conditions, such as pH and ligand concentration (both organic and inorganic), may be different.
8. Present levels of transuranium elements in our environment have not produced discernible ecological effects.

We will see examples of the types of work leading to these conclusions as we proceed through these chapters on the environment.

F. Tritium in the Environment

In chapter 10, we engaged in a detailed consideration of tritium and its compounds as a possible inhalation hazard. We also considered briefly the possibilities for transmutational effects at the cellular and whole-organism level. In chapter 20, we will consider the potential for effects of tritium when it is combined into important biomolecules. Yet, despite all of this coverage, the considerable effort expended in ascertaining how tritium behaves in the

(a) As indicated earlier, the complete table of contents of this book is given as note 4 at the end of this chapter.

(b) This conclusion must be regarded as still moot.

environment needs reviewing as a special topic here. This holds, even though the effort has brought few surprises.

The research and field results show, as expected, that tritium is widely disseminated and very transportable in general. If there were not so much tritium produced in the nuclear fuel cycle, probably much less attention would have been paid to understanding its behavior in the environment. However, with megacuries produced and few processes available for efficiently sequestering it permanently, it would not take a very large concentration factor in the environment to develop potentially significant doses. Therefore, a considerable effort was made, and that is the subject of this section. The workers and laboratories are primarily those we have already met.

Global levels of tritium and its compounds obviously increased during the years of atmospheric weapons testing, especially when fusion devices were involved. The nuclear fuel cycle makes its contribution of tritium and its compounds largely from reprocessing plants and certain types of reactors, especially those moderated with heavy water (e.g., in Canada).

In the early days (1950s, early 1960s), discussions of environmental contamination from radionuclides seldom singled out tritium. Strontium, cesium, etc., came in for much more attention. The programs for both of the Atoms for Peace Conferences in the 1950s have little on tritium, much more on strontium and cesium. While the earlier annual reports from the laboratories, e.g. Hanford, describe experiments on individual organisms and point out such phenomena as the oxidation of tritium by bacteria, uptake by bean roots, and the like, the orientation was only obliquely environmental. Even the first major symposium on radioisotopes in the biosphere (Caldecott and Snyder 1960) did not devote an identifiable section to tritium, partly because the discussions were mostly generic and not oriented toward specific radionuclides.^(a)

At the first National Radioecology Symposium (section IV), there was a review from the University of Connecticut Marine Research Laboratory called "Tritium in Ecology" (Skauen 1963). This was part of a section recording the role of several radionuclides in ecology. It considered geology, bacteriology, zoology, botany, and work with man but did not do much integrating of the subject. It does show, however, by the listing of 155 titles in the bibliography, that the subject was beginning to attract attention.

It appears that the U.S. PHS may have led off significant general interest in tritium in the environment *per se* as contrasted to individual organisms. It started with the expected expansion of the nuclear power industry. Peterson et al. from the Bureau of Radiological Health presented estimates of environmental contamination with tritium up to the year 2000 at an IAEA symposium in Vienna (Peterson et al. 1969). Before long, such reports became numerous since the PHS operated a tritium surveillance network, and others followed. Data included tritium from nuclear reactors, nuclear testing, fuel reprocessing, waste disposal, etc. The possible public health significance of the known and postulated releases in the opinion of Peterson et al. (1969) follows:

(a) One of the reasons for the slow start with tritium is that its production in nuclear fission, in contrast to being an activation product, was not fully appreciated until the later 1950s (Albenesius 1959; Albenesius and Ondrejcin 1960).

7.0 Public Health Significance

The principal form of tritium in reactors is tritiated water and conventional concentration processes such as ion exchange and evaporation do not remove appreciable amounts of tritium from liquid effluents. For this reason, tritium may comprise between 50 and almost 100% of the total activity in reactor discharges to the environment. The Radioactivity Concentration Guide (RCG) for tritium, however, is much higher than for most common fission products. The RCG for tritium is 10^{-3} $\mu\text{Ci/ml}$ and because of its short biological half-life (12 days), its low disintegration energy, and uniform distribution in the body, its relative health significance is smaller than for other fission products such as ^{90}Sr and ^{137}Cs .

The estimated tritium release from a 1000 MW(e) pressurized-water reactor is approximately 7000 curies per year (average of Table V). Plants employing single-pass condenser systems to remove excess heat have circulation rates of about 1.5×10^{15} cm^3 per year and the resulting concentration would be about 5×10^{-6} $\mu\text{Ci/ml}$ or 0.5% of the RCG for exposure of the general population (10^{-3} $\mu\text{Ci/ml}$). The volume of water discharged from reactors employing cooling towers is considerably smaller and may be only 2000 gallons per minute. Under these circumstances the effluent concentration could approach 20% of the guideline value. Under certain circumstances it may be necessary to restrict discharges or to provide supplementary dilution for these plants.

The Public Health Service operates a tritium surveillance network in the United States to provide information on nationwide trends and tritium concentrations in water downstream from large nuclear installations. The results reported by this network are published periodically. Present levels are 0.2-10 nCi/l and the dose contribution from the maximum concentration has been estimated to be less than 1.6 mrem/year.

The buildup of tritium in small confined bodies of water may approach concentrations approximately 20% of the RCG which suggests that environmental surveillance would be indicated to monitor this accumulation. Our predictions for Lake Michigan show that the tritium concentrations in the Lake will be about 40 nCi/l, most of which will be contributed by the reactors on the Lake. Continuous consumption of this water for a fifty-year period would result in a total integrated dose of only 350 mrem, which is considerably less than that from natural radiation sources. (Peterson et al. 1969. Reference citations have been omitted.)

Pressures for a more comprehensive review of all aspects of tritium, including its environmental behavior, were mounting in and out of Washington. Soon the AEC sponsored a critical review of tritium sources and its behavior in the environment. It was written by Jacobs and published in 1968 (see references for chapter 10). The AEC also sponsored, with the EPA, a large symposium held in Las Vegas in 1971 edited by Moghissi and Carter and published in 1973.

One of the questions in the investigators' minds was still, "Will tritium show a positive concentration factor comparable to those seen for many other radionuclides in the environment?" The answer is not simple, but several papers at the symposium shed light on the subject.

A review by Bruner from AEC (1973) compared specific activities of samples of many invertebrate organisms (including separated out "bound" and "free" portions of tritium) to similar data from the hydrosphere. He concluded that invertebrates in general do not enrich the organic fractions of their tissues with tritium from the environment. (Specific activities varied with time depending on the amount of fallout present.) A puzzling exception to this generalization was the water flea, *Daphnia*. It showed a ratio between dry tissue and tritiated food of over four. However, the roster of organisms surveyed by Bruner included phytoplankton, zooplankton, mollusks, water plants, and other flora and insects,

and there were no other exceptions. Several even showed what appeared to be discrimination against tritium.

Other papers at this symposium and a general literature review done slightly earlier by Elwood (1971) made it clear that most of the tritium (as tritiated water) is distributed rapidly and uniformly throughout the body water of animals and approaches equilibrium with the environmental concentration in a few hours. In plants, it usually takes longer to reach equilibrium. In both cases, a small fraction can be bound to organic molecules either directly or by entering the system from the environment in bound form. This portion, of course, has a much longer retention time than unbound tritium. Thus, the chemical form at the time of arrival makes a real difference, as discussed by Kirchmann et al. (1973) but not necessarily to the extent needed to support a positive concentration factor.

By contrast, Cohen and Kneip (1973) from New York University, working around the Indian Point pressurized water reactor on the Hudson River estuary reported tritium concentrations (in picocuries per liter) in sediment ten times higher than in the ambient water, four times higher in fish, and three times higher in rooted aquatic plants. They were well aware that such an apparent concentration factor might reside in part in varying concentrations of the discharge and the fact that the system was not in a steady state. Indeed, the authors postulated an "inheritance" of organically labeled compounds as a possible mechanism for accumulation of tritium in biota above ambient concentrations.

Concentration factors may not be as important to know in the case of tritium as uptake and transfer rates and retention factors. The group at Lawrence Livermore Laboratory has expended much effort in obtaining such factors. At the tritium symposium, Koranda and Martin (1973)^(a) studied the movement of tritium in soil systems from the Sedan shot^(b) crater at the NTS and also in an experimental cornfield near Livermore, using tritium injected into the soil beneath the plants at different depths. It was clear that the half-life of tritium in soil is longer than in most other components of the ecosystem.

The Livermore people also looked at tissue-water and tissue-bound tritium in plants exposed to tritiated water vapor and measured uptake coefficients and retention determined over both short- and long-term exposures. The three component retention curves described for vertebrates in chapter 10 were seen in the plant material studied.

The work was extended to ecosystems in a tropical rain forest of Puerto Rico and the passage through small mammals over several generations in the Sedan crater (Jordan et al. 1970; Martin et al. 1970; Martin and Koranda 1971).

The conclusions were that tritium movement in ecosystems is complex. Many different compartments seem to be involved. On balance, however, rapid movement^(c) of the bulk of the tritium is as characteristic of environmental receptors as of the animals described in chapter 10, with always a small but significant fraction in bound form.

(a) Many of the reports from Livermore cited in this section appeared also, sometimes in greater detail, as UCRL reports.

(b) One of the "Plowshare" shots—chapter 14.

(c) Koranda and Martin give half-times in plants as generally shorter than in animals, in contrast to the conclusions of Elwood cited above. The differences are not large, however.

Turning to aquatic systems, the Lawrence Livermore investigators (Harrison, Koranda, and Tucker 1973) studied uptake of tritium in an artificial marine pool by clams, crabs, and fish. The kinetics of uptake and loss showed rapidly and slowly exchangeable fractions in all soft tissues and permitted construction of a model to predict changes in tissue-bound tritium with changes in exposure concentrations.

The modeling was extended to calculation of the dose to man (Moghissi, Patzer, and Carter 1973), via food-chain transfer to man (Anspaugh et al. 1973), and to a model for calculating guidance for limiting environmental releases of tritium on the basis of the calculated dose to man (Rohwer, Kelly, and Booth 1973). For the latter, a system known as "CUEX"^(a) was developed, which we will consider in connection with the Plowshare project.

John Strand and William Templeton, at PNL, examined the possibility of the late effects from tritium radiation on embryogenesis,^(b) using the fertilized eggs of rainbow trout. In a series of studies (Strand et al. 1973, 1977, 1982; Strand, Templeton, and Tangen 1971; Strand, Templeton, and Olson 1976; and Strand and Thompson 1976), they and their colleagues conclusively showed that the primary immune response in this fish species was suppressed at 4-rad doses after challenge with the ubiquitous fish pathogen, *Flexobacter columnaris*. The dose-response curve was exponential from 0.04 to 40 rad, indicating that these effects could be reliably extrapolated to the lower dosages. Their studies are interesting in that the 4-rad dose corresponded to a 20-day exposure to the then-accepted maximum permissible concentration (MPC) of 0.1 $\mu\text{Ci}/\text{ml}$. Secondary challenge of the fish, seventeen months later, showed that the impairment was irreversible, although the dose levels are considerably higher than one would expect to find environmentally. Strand examined other features, also, such as growth, developmental abnormality, mortality, and evidence for tritium accumulation ratios in excess of 1.0. With the exception of immune suppression, no other significant findings were noted.^(c)

In 1977, the EPA developed very broad projections concerning environmental contamination with radionuclides, including tritium (EPA 1977).

The next large crop of pertinent reports on tritium in the environment came in 1979 and 1980. Of primary interest are the NCRP report, *Tritium in the Environment* (NCRP 1979), the IAEA symposium on the Behavior of Tritium in the Environment (IAEA 1979b), and an experts' report to the Nuclear Energy Agency (NEA) of the Organization for Economic Cooperation and Development (NEA 1980). The NCRP report is an especially concise and readable summary with full documentation. The IAEA symposium contained individual papers from worldwide sources.^(d) The NEA review provides useful comparative data for four radionuclides that distribute in the environment as gases or as airborne particles, viz., tritium, ^{14}C , ^{85}Kr , and ^{129}I .

The NCRP report reiterates the presence of at least three pools for tritium in individuals, with half-lives as described in chapter 10. They add to this information three different compartmental models for the environment. There is a simplistic one-compartment model comprising the circulating waters of the world

(a) Cumulative Exposure Index.

(b) Remember the similar work on rodents in the laboratory done by Cahill (chapter 10).

(c) This paragraph supplied by Dr. Burton Vaughan.

(d) The table of contents of this symposium appears as note 5 at the end of this chapter.

with which man maintains equilibrium. Using a dose-rate factor of 0.095, μrad for 1 pCi/l/yr, the tissue dose rate from a megacurie-per-year release is calculated worldwide and also to the Northern Hemisphere and to the area between latitudes 30° and 50° north. A more realistic three-compartment model considers the atmosphere, land surface, and ocean surface waters. The same type of calculations for dose rate are made. Finally, a complex seven-compartment model with the needed additional transfer coefficients is given. This adds deep groundwater, deep ocean water, surface soil water, and saline lakes and inland seas to the compartments of the three-component model.

For each model, it was necessary to estimate the volume of each compartment and the mean residence time (volume divided by the rate of entrance into and egress from the compartment). The dose rates per megacurie released are all in the microrad-per-year range and are roughly comparable between the three-compartment and seven-compartment models, but considerably lower on a world basis with the one-compartment model. These very low dose rates are consistent with what has been said about tritium already from individual dose calculations. However, we should not forget that very large amounts of tritium can be released in an active nuclear fuel cycle, and tritium cannot be disregarded, as Gofman has stated (1981).

By the time of the NCRP report, the question of whether or not a significant concentration factor exists for tritium had been resolved in the negative. What appeared earlier as concentration processes were considered by the NCRP committee to be due to differences in residual specific activity of certain tissues and organs, particularly some with high concentrations of liquid and fat. Since these were still well below the specific activity of the tritiated water from which the deposit was derived, no true concentration process was considered to be involved. In view of the large amounts of tritium potentially invading the biosphere, it is fortunate that concentration factors such as those seen with many radionuclides such as the actinides do not exist.

The IAEA symposium devoted over seven hundred pages to tritium in the environment and thus cannot help but emphasize the level of interest and effort attracted to the subject on an international scale. Many of the reports concern behavior in individual organisms and have already been mentioned in chapter 10. Much of the work concerns releases from various nuclear facilities. Some concern laboratory investigations, particularly with aquatic organisms in both fresh- and salt-water ecosystems, including several we have already discussed (White Oak Lake, Savannah River Estuary, Irish Sea). Some are mechanistic and concern movements in soil, the atmosphere, plants, and trees, and some concentrate on analysis of pathways. The distribution among countries, laboratories, and subjects is very broad, as is indicated by the table of contents of this symposium (with country of origin added) as shown in note 5.

Somewhat unexpected were the potential tritium releases to the environment from consumer products such as radioluminous compounds in paint or plastic and electrical and electronic devices.^(a) Wehner (1979) estimated that an expected liberal exemption policy for the construction and disposal of such devices could lead to cumulative doses in excess of those from the nuclear power industry, at least in the Federal Republic of Germany. Combs and Doda

(a) As we saw in chapter 10, tritium gradually took over from ^{226}Ra in the luminous paint industry because of the health problems with radium.

(1979) from the U.S. NRC indicated that one million curies (1 MCi) of tritium were distributed in 1977 for backlighting the liquid crystal displays in digital electronic watches. This can be compared to 3 MCi from power reactors and 6 MCi produced naturally. Thus, the NRC feels that careful environmental study of the production, and especially the disposal, of these consumer products is necessary.

We will close this consideration of tritium in the environment with a brief discussion of the NEA experts' report (NEA 1980). As indicated, the report considers ^{14}C , ^{85}Kr , and ^{129}I as well as tritium. It is a very handy summary of the source terms for each, assessment of radiation doses for these radionuclides when emitted to the environment, the maximum dose equivalents to the most exposed individuals, collective dose equivalent commitments, and matters of management and cost-effectiveness. The membership is shown at the end of this chapter (note 6).

Of most interest at this point is the comparison of maximum dose and of collective dose equivalent commitment^(a) for these four mobile radionuclides when emitted to the environment. Figures 11.14A and B show these calculated figures. The number of terms and complex models needed to arrive at figures like those given above is very large.^(b) The fact that it can be done with a modicum of assurance (the uncertainties are still large, as indicated in a special section of the report) attests to the great amounts of information accumulated for environmental behavior as well as dosimetry of these substances.

It is of interest that the local exposure from the fuel reprocessing plant was the largest for all four isotopes in terms of the maximum dose equivalent rates, while the heavy water reactor contributed the most in the case of both tritium and ^{14}C when collective dose equivalent commitment is calculated. It is also noteworthy that the boiling water reactor is the lowest of the group in dose associated with tritium.

In chapter 15, we will have an opportunity to look in somewhat more detail at the environmental pathway assumptions and data that go into making calculations such as those resulting in figure 11.14A and B.

G. The Environmental Impact Statement

We will review historically the genesis of the EIS in chapter 16. Enactment of the National Environmental Policy Act (NEPA) by the U.S. Congress was specifically triggered by plans to build a nuclear power plant on Chesapeake Bay, and AEC and ERDA had to meet the requirements of the act. We have just considered some aspects of the report, WASH-1535 (AEC 1974, 1975), the environmental impact statement for the LMFBR program. While this may be one of the most voluminous and most thoroughly discussed and reviewed of such statements, many others are almost as comprehensive and detailed. They changed the

(a) Dose equivalent commitment times the population size.

(b) Pamela Bryant from the U.K. National Radiological Protection Board apparently spearheaded this review for the NEA. She produced a very broad paper to lead off an IAEA symposium in 1979. This includes the modeling for tritium, ^{14}C , ^{85}Kr , and ^{129}I . For tritium, the regional populations included were around Lakes Erie and Ontario and the St. Lawrence River, the Northeast Irish Sea, and the Baltic Sea. For the other nuclides, fewer sample populations were included. This presentation (Bryant 1979) is an important complement to the NEA document.

FIGURE 11.14A. (Left) Values of the maximum dose rates from four principal radionuclides to the most exposed individuals from local, regional and global sources. Emissions of tritium from reactors are to both hydrosphere and atmosphere; other emissions are to atmosphere only. Total emissions of tritium and ^{129}I from FRPs to salt water in particular regions are estimated to result in the local and regional maximum dose rates shown by the dashed lines. The components of the maximum dose rates from tritium emitted totally to salt water at reactors are also shown by dashed lines (from NEA 1980).

FIGURE 11.14B. (Right) The collective dose-equivalent commitments, in Sv, for four radionuclides that can be avoided by complete retention and isolation for 10^4a of radionuclides that would otherwise be emitted. Emissions are to the atmosphere except for tritium from reactors for which emissions to both the atmosphere and hydrosphere have been assumed. The dashed lines show the estimated commitments avoided if emissions of tritium and ^{129}I from particular facilities are totally to sea water (from NEA 1980).

entire mechanism by which environmental concerns were accommodated in the planning process.^(a)

The growing need to prepare these statements galvanized much action in environmental research and in the projection of population doses from multifarious activities.^(b) Each statement bears theoretically on a specific site and process or set of processes. In the early phases, very careful analyses were made of meteorology, geology, ecology, hydrology, etc. of the specific site concerned. As the pressures rose, many statements became more generic in nature. They used the characteristics of the site, but many of the underlying calculations, such as population dose, became more or less standardized. Thus, the research and development efforts described in the earlier sections of this chapter that had become more or less generic were brought to bear on a variety of environmental impact statements in a variety of settings.

The existence of these large repositories of information must be noted and readers informed that they will find in these documents much of specific interest to research on the health effects of radionuclides. There is no doubt that the need for the EIS underscored the research information that was needed and stimulated new projects, even though the amount of new information from one EIS to the next is not large.

VII. Summary and Commentary

This chapter, the first of five concerned with research bearing on radionuclides in the environment, has reviewed what was almost another new dimension—the work around the major production sites.

It began with the very early concern for the fisheries in the Pacific Northwest that developed when the decision was made to locate the plutonium production reactors on the Columbia River at Hanford, Washington. The first work was done in the early 1940s at the Applied Fisheries Laboratory of the University of Washington, even before the Hanford reactors were built. It extended to studies on the river itself and the development of an ecology group at Hanford. This group eventually worked with terrestrial contamination problems as well as those in the aquatic environment. It was a large and significant effort that resulted in learning much about the radiobiology of salmon and trout, the fact that the pile effluents were toxic primarily because of chemical toxins released rather than the radioactivity, and the broad conclusion that the operation of the plant had not had, nor would it be expected to have, a significant deleterious effect on the fisheries of the Pacific Northwest. We associate with this work the names Lauren Donaldson, Allyn Seymour, Arthur Welander, and others at the University of Washington; Richard Foster, Jerry Davis, Wayne Hanson, Harry Kornberg and associates at Hanford. This was the only substantive environmental research (as compared to monitoring) done around the sites during World War II.

(a) While the edict of Congress and the enactment of NEPA caused a review of plans for the Calvert Cliffs Plant on Chesapeake Bay, many ecologists regard the voluminous tome prepared for the proposed "Operation Chariot" in Alaska (in later chapters) as the first full-blown de novo environmental impact statement.

(b) An important criterion is whether or not the proposed activity is "major" or "federal." Guidance on such decisions is available in, for example, the book by Heer and Hagerty (1977). Most of the activities we are considering are both "major" and "federal."

Soon after World War II, the contamination of White Oak Lake stimulated the development of a small ecology group at Oak Ridge. The development was pushed by Karl Morgan, head of the Health Physics Division, and it grew under the tutelage of Stanley Auerbach into a large and prestigious ecology program. While there was considerable interest in the aquatic system of White Oak Lake and the Clinch River, the Oak Ridge effort involved much terrestrial as well as aquatic ecology.

While Hanford and Oak Ridge were the original sites with substantive ecology programs, many others developed in the postwar years. Some of these were outgrowths of local site-specific problems (Brookhaven, Idaho Falls, Rocky Flats, Savannah River); others had a broader base (Colorado State University, Health and Safety Laboratory in New York, Lawrence Livermore, Los Alamos, New York University, the University of California at Los Angeles, and others). One result of this activity was the designation of a new specialty—radioecology. The genesis and development of the field and the contents of the major symposia associated therewith are described in the chapter.

The number and variety of organisms studied were greatly expanded by the need to do environmental studies. Plant systems and aquatic forms came in for much more attention than in the laboratory-oriented investigations. Furthermore, ecosystems entered the picture and have proven to be one of the more difficult aspects of the field. Probably the ecosystem approach needs more attention in the future than any other aspect. Yet, it is a complex and expensive enterprise. The chapter has questioned whether or not we are prepared to do what is really needed.

The chapter concludes with a review of some special topics whose origins can be traced to the work around the production sites. These include marine radioecology, possible effects of radionuclides in ecosystems, consideration of site-specific problems around nuclear reactors, transuranic nuclides in the environment, and prospective studies such as the Liquid Metal Fast Breeder program.

It was around the production sites that the field of radioecology was born. If the chapter does nothing else, it should make it apparent that concern for the environmental impact of the production of radionuclides was a top priority from the earliest days and that any mistakes that were made must be chalked up to lack of knowledge and not to crass disregard for the environment.

Note 1—Contents of First National Symposium on Radioecology^(a)

Introductory Speaker

Impact of Atomic Energy on the Environment and Environmental Science—
John N. Wolfe

I. General Review Papers

Radiation Effects and Peaceful Uses of Atomic Energy in the Plant and Soil Sciences—John D. Spikes

Radiation Effects and Peaceful Uses of Atomic Energy in the Animal Sciences: Radiation and Biologic Capability—Paul S. Henshaw

Continental Close-in Fallout: Its History, Measurement and Characteristics—Kermit H. Larson

(a) Schultz and Klement (1963).

Disposal of Radioactive Wastes: Its History, Status and Possible Impact on the Environment—Donald W. Pritchard and Arnold B. Joseph

II. Cycling and Levels of Radionuclides in the Terrestrial Environment

Some Effects of Environmental Factors Upon Accumulation of World-Wide Fallout in Natural Populations—J. J. Davis, W. C. Harrison and D. G. Watson

Vegetational Analyses in a Creosote Bush Community and Their Radioecologic Implications—William H. Rickard

Biological Availability of Strontium-90 to Small Native Animals in Fallout Patterns from the Nevada Test Site—J. W. Neel and K. H. Larson

The Dynamics of Fallout Distribution in a Colorado Alpine Tundra Snow Accumulation Ecosystem—William S. Osburn, Jr.

Accumulation of Strontium-90 in Yearling Columbian Black-Tailed Deer, 1950-1960—Vincent Schultz and William M. Longhurst

Environmental Pathways of Radioactive Iodine from Nuclear Tests in Arid Regions—Norman R. French and K. H. Larson

Accumulation and Cycling of Organic Matter and Chemical Constituents during Early Vegetational Succession on a Radioactive Waste Disposal Area—H. R. DeSelm and R. E. Shanks

Factors Related to Concentration of Radiocesium in Plants Growing on a Radioactive Waste Disposal Area—R. E. Shanks and H. R. DeSelm

Movement and Accumulation of Radiostrontium and Radiocesium in Insects—D. A. Crossley, Jr.

Estimation of Dose Rate and Equilibrium State from Bioaccumulation of Radionuclides by Mammals—Stephen V. Kaye and Paul B. Dunaway

Experimental Isolation of Food Chains in an Old-Field Ecosystem with the Use of Phosphorus-32—Eugene P. Odum and Edward J. Kuenzler

Analog Computer Models for Movement of Nuclides through Ecosystems—Jerry S. Olson

Cycling of Cesium-134 in White Oak Trees on Sites of Contrasting Soil Type and Moisture. I. 1960 Growing Season.—John P. Witherspoon, Jr.

III. Cycling and Levels of Radionuclides in the Marine Environment

Cycling and Levels of Strontium-90, Cerium-144 and Promethium-147 in the Atlantic Ocean—Vaughan T. Bowen and Thomas T. Sugihara

Gross Beta Radioactivity in Marine Organisms—Thomas W. Hatfield, Donald M. Skauen and John S. Rankin, Jr.

Radionuclides in Plankton and Tuna from the Central Pacific—F. G. Lowman

Radioactivity of Marine Organisms from Guam, Palau and the Gulf of Siam, 1958-1959—Allyn H. Seymour

Zinc-65 in Oysters in Fishers Island Sound and Its Estuaries—Bryant W. Fitzgerald and Donald M. Skauen

Experimental Studies of the Turnover of Phosphate in Marine Environments—Lawrence R. Pomeroy

Qualitative Distribution of Radionuclides at Rongelap Atoll—E. E. Held

Availability of Sediment-Sorbed Materials to Marine Biota—T. W. Duke, E. R. Ibert and K. M. Rae

Micro-organisms in Environments Contaminated with Radioactivity—James B. Lackey and Carrie F. Bennett

The Role of Phytoplankton in the Cycling of Radionuclides in the Marine Environment—T. R. Rice

The Uptake, Accumulation and Exchange of Strontium-90 by Open Sea Phytoplankton—E. F. Corcoran and J. F. Kimball, Jr.

The Effect of Environmental Ions on the Concentration of Radiocalcium and Radiostrontium by Euryhaline Teleosts—Sidney J. Townsley

IV. **Cycling and Levels of Radionuclides in the Freshwater Environment**

The Strontium and Calcium Relationships in Clinch and Tennessee River Mollusks—D. J. Nelson

The Fate of Radiostrontium in a Freshwater Community—Ivan L. Ophel

Translocation of Phosphorus in a Trout Stream Ecosystem—Robert C. Ball and Frank F. Hooper

Natural Radioactivity in the Food Web of the Banded Sculpin *Cottus carolinae* (Gill)—W. L. Minckley, J. E. Craddock and L. A. Krumholz

Radium in Natural Waters in the United States—Robert C. Scott

V. **Effects of Ionizing Radiation on Plants and Animals in Terrestrial Environments**

Ecological Effects of Ionizing Radiation on Organisms, Communities and Ecosystems—Robert B. Platt

Prediction of the Sensitivity of Plants to Chronic Gamma Irradiation—Arnold H. Sparrow and George M. Woodwell

Changes in a Herbaceous Plant Community During a Three-Year Period Following Exposure to Ionizing Radiation Gradients—Frank McCormick

A Study of Succession in Fields Irradiated with Fast Neutron and Gamma Radiation—Charles P. Daniel

Effects of Radiation from an Air-Shielded Reactor on Forest Litter Production—John T. McGinnis

The Effect of Ionizing Radiation on *Smilax* with Special Reference to the Protection Afforded by Their Production of Underground Vegetative Structures—Hedley G. Chappell

Effects of Ionizing Radiation on *Pinus taeda* L.—Robert A. Pedigo

Factors Affecting Tree Seed and Seedling Radiosensitivity—Margaret B. Heaslip

Recovery of Vegetation on Atomic Target Areas at the Nevada Test Site—Lora Mangum Shields and Philip V. Wells

Radiation Dosages in the Vicinity of an Unshielded Nuclear Reactor—James J. Cowan and Robert B. Platt

Influence of Four Rocky Mountain Regional Environments on Pea Plants Grown from Irradiated Seeds—William S. Osburn, Jr.

Natural Radiation Effects of Vertebrate Animals Inhabiting the Uranium Areas of Southeastern Utah—Wilmer W. Tanner

Comparative Ecological Studies of Animals at the Nevada Test Site—Donald M. Allred and D. Elden Beck

Effects of Ionizing Radiation on Mammal Populations on the White Oak Lake Bed—Paul B. Dunaway and Stephen V. Kaye

The Effect of Neutron-Gamma Radiation on Free-Living Small Mammals at the Lockheed Reactor Site—Jay H. Schnell

Relative Sensitivity of Nestlings of Wild Passerine Birds to Gamma Radiation—William K. Willard

VI. Effects of Ionizing Radiation on Plants and Animals in Marine and Freshwater Environments

Increase in Radioresistance of Fish to Lethal Doses with Advancing Embryonic Development—Kelshaw Bonham and Arthur D. Welander

Effect of Chronic Feeding of Sr^{90} - Y^{90} on Rainbow Trout—R. E. Nakatani and R. F. Foster

The Effects of Continuous, Sub-lethal Gamma Radiation on the Intrinsic Rate of Natural Increase and Other Population Attributes of *Daphnia pulex*—J. S. Marshall

The Preliminary Investigation of Salivary Gland Chromosomes of *Chironomus tentans* Fabr. from the Clinch River—D. J. Nelson and B. G. Blaylock

Effects of Uranium Mill Wastes on Biological Fauna of the Animas River (Colorado-New Mexico)—J. B. Anderson, E. C. Tsivoglou and S. D. Shearer

Exploratory Study of Radiation Damage in the Thyroids of Coral Reef Fishes from the Eniwetok Atoll—Aubrey Gorbman and Miriam S. James

VII. Ecological Techniques Utilizing Radionuclides in Terrestrial Environments

Radioactive Tracers as an Aid to the Measurement of Energy Flow at the Population Level in Nature—Eugene P. Odum and Frank B. Golley

Tracer Studies of the Breakdown of Forest Litter—J. S. Olson and D. A. Crossley, Jr.

Methods for Introducing Radionuclides into Plants—T. W. Sudia and A. J. Linck

Consumption of Vegetation by Insects—D. S. Crossley, Jr.

Use of Radionuclides in Ecological Studies of Insects—Dale W. Jenkins

The Role of Radionuclides in Insect Behavior Studies—Claude H. Schmidt and Carroll N. Smith

Techniques for Studying Movements of Vertebrates in the Field—John R. Tester

A Method of Measuring Waterfowl Dispersion Utilizing Phosphorus-32 and Zinc-65—W. C. Hanson and A. C. Case

Use of the Jack Rabbit as a Bio-indicator of Environmental Strontium-90 Contamination—Z. M. Fineman, R. McBride and J. Detmer

VIII. Ecological Techniques Utilizing Radionuclides in Marine and Freshwater Environments

Biological and Physical Transport of Radionuclides in Stratified Lakes—Arthur D. Hasler and Gene E. Likens

Use of Light Nuclides in Limnology—Edward S. Deevey, Jr., Minze Stuiver and Nobuyuki Nakai

Evaluation of the Carbon-14 Technique for Measurement of Primary Production—M. B. Allen

Use of Nitrogen-15 for Measurement of Rates in the Nitrogen Cycle—John C. Neess, Richard C. Dugdale, John J. Goering and Vera A. Dugdale

Zinc-65 in Studies of the Freshwater Zinc Cycle—Roger W. Bachmann

IX. The Occurrence, Effect and Utilization of Nuclides in the Environment

Manganese in Ecology—Peter J. Wangersky

Biological and Environmental Behavior of Ruthenium and Rhodium—S. I. Auerbach and J. S. Olson

Reactions of Tungsten in Soils and Its Uptake by Plants—E. M. Romney and J. D. Childress

The Radioecology of Calcium—Sidney C. Hsiao

Factors Controlling the Distribution of the Rare Earths in the Environment and in Living Organisms—Ralph F. Palumbo

Cesium and Its Relationships to Potassium in Ecology—J. J. Davis

Review and Discussion of Barium—Norman R. French

Iron and Cobalt in Ecology—F. G. Lowman

Environmental Behavior of Chromium and Neptunium—Richard F. Foster

Some Aspects of the Biology of Zirconium-95—Edward E. Held

Iodine in the Environment—W. C. Hanson

Tritium in Ecology - A Review—Donald M. Skauen

The Natural Radioactive Series in Organic Material—F. F. Koczy

Arsenic and Its Radioisotopes in the Environs—R. L. Junkins

Review of Zinc in Ecology—T. R. Rice

Plutonium, Its Biology and Environmental Persistence—J. H. Olafson and K. H. Larson

APPENDIX

Panel Discussion on Education and Research Training—Eugene P. Odum, Moderator

FOREWORD

PREFACE

ACKNOWLEDGMENTS

CONTRIBUTORS

SYNTHESIS OF THE RESEARCH LITERATURE

R.L. Watters, D.N. Edgington, T.E. Hakonson, W.C. Hanson, M.H. Smith, F.W. Whicker, and R.E. Wildung

(a) W. C. Hanson, Ed. (1980).

INTRODUCTION

Radiological Assessments, Environmental Monitoring, and Study Design
Wayne R. Hansen and Donald R. Elle

SOURCE TERMS

Worldwide Fallout
R.W. Perkins and C.W. Thomas

Transuranic Elements in Space Nuclear Power Systems
Thaddeus J. Dobry, Jr.

Quantities of Transuranic Elements in the Environment from Operations Relating to Nuclear Weapons
Gordon Facer

Transuranic Wastes from the Commercial Light-Water-Reactor Cycle
M.R. Kreiter, J.E. Mendel, and R.W. McKee

INVENTORY AND DISTRIBUTION

The Detection and Study of Plutonium-Bearing Particles Following the Reprocessing of Reactor Fuel
S. Marshall Sanders, Jr., and Albert L. Boni

Physicochemical Associations of Plutonium and Other Actinides in Soils
E.A. Bondietti and T. Tamura

Sources of Variation in Soil Plutonium Concentrations
John E. Pinder III and Donald Paine

Statistics and Sampling in Transuranic Studies
L.L. Eberhardt and R.O. Gilbert

Appropriate Use of Ratios in Environmental Transuranic Element Studies
P.G. Doctor, R.O. Gilbert, and J.E. Pinder III

TERRESTRIAL ECOSYSTEMS

Experimental Studies

Review of Resuspension Models
J.W. Healy

Transuranic and Tracer Simulant Resuspension
G.A. Sehmel

Interaction of Airborne Plutonium with Plant Foliage
D.A. Cataldo and B.E. Vaughan

The Relationship of Microbial Processes to the Fate and Behavior of Transuranic Elements in Soils, Plants, and Animals
R.E. Wildung and T.R. Garland

Uptake of Transuranic Nuclides from Soil by Plants Grown Under Controlled Environmental Conditions
D.C. Adriano, A. Wallace, and E.M. Romney

Comparative Uptake and Distribution of Plutonium, Americium, Curium, and Neptunium in Four Plant Species
R.G. Schreckhise and J.F. Cline

Field Studies

Comparative Distribution of Plutonium in Contaminated Ecosystems at Oak Ridge, Tennessee, and Los Alamos, New Mexico
Roger C. Dahlman, Charles T. Garten, Jr., and Thomas E. Hakonson

Plutonium Contents of Field Crops in the Southeastern United States
D.C. Adriano, J.C. Corey, and R.C. Dahlman

Ecological Relationships of Plutonium in Southwest Ecosystems
T.E. Hakanson and J.W. Nyhan

Plutonium in a Grassland Ecosystem
Craig A. Little

Transuranic Elements in Arctic Tundra Ecosystems
Wayne C. Hanson

Models

Nevada Applied Ecology Group Model for Estimating Plutonium Transport and Dose to Man
W.E. Martin and S.G. Bloom

A Model of Plutonium Dynamics in a Deciduous Forest Ecosystem
Charles T. Garten, Jr., Robert H. Gardner, and Roger C. Dahlman

AQUATIC ECOSYSTEMS

Marine Studies

A Review of Biokinetic and Biological Transport of Transuranic Radionuclides in the Marine Environment
T.M. Beasley and F.A. Cross

Geochemistry of Transuranic Elements at Bikini Atoll
W.R. Schell, F.G. Lowman, and R.P. Marshall

Transuranium Radionuclides in Components of the Benthic Environment of Enewetak Atoll
V.E. Noshkin

Plutonium and Americium Behavior in the Savannah River Marine Environment
D.W. Hayes and J.H. Horton

Freshwater

Patterns of Transuranic Uptake by Aquatic Organisms: Consequences and Implications
L.D. Eyman and J.R. Trabalka

The Migration of Plutonium from a Freshwater Ecosystem at Hanford
Richard M. Emery, Donald C. Klopfer, and M. Colleen McShane

Plutonium in Rocky Flats Freshwater Systems
D. Paine

Plutonium in the Great Lakes
M. A. Wahlgren, J.A. Robbins, and D.N. Edgington

Transport of Plutonium by Rivers
H.J. Simpson, R.M. Trier, and C.R. Olsen

BIOLOGICAL EFFECTS

Biological Effects of Transuranic Elements in the Environment: Human Effects and Risk Estimates
Roy C. Thompson and Bruce W. Wachholz

Ecological Effects of Transuranics in the Terrestrial Environment
F.W. Whicker

Dosimetry and Ecological Effects of Transuranics in the Marine Environment
William L. Templeton

INDEX

Note 5—Table of Contents of International Symposium on Behavior of Tritium in the Environment. International Atomic Energy Agency, Vienna, (a) 1979

DISTRIBUTION OF TRITIUM (Session 1 and Session 2, Part 1)

Atmospheric HT and HTO: V. Distribution and large-scale circulation (IAEA-SM-232/62)
A.S. Mason, H.G. Östlund
[United States (Miami)]

Evidence of pulsed discharges of tritium from nuclear energy installations in Central European precipitation (IAEA-SM-232/18)
W. Weiss, J. Bullacher, W. Roether
[Federal Republic of Germany]

Artificial tritium fall-out at the South Pole (IAEA-SM-232/38)
J. Jouzel, M. Pourchet, C. Lorius, L. Merlivat
[France]

Distribution and reactions of tritiated hydrogen and methane (IAEA-SM-232/54)
L.L. Burger
[United States (PNL)]

Tritium pollution in the Swiss luminous compound industry (IAEA-SM-232/11)
K. Krejčí, A. Zeller, Jr.
[Switzerland]

Discharge of tritium to the environment from unrestricted use of consumer products containing this radionuclide (IAEA-SM-232/9)
G. Wehner
[Federal Republic of Germany]

Large-scale distribution of tritium in a commercial product (IAEA-SM-232/57)
F. Combs, R.J. Doda
[United States (NRC)]

EVALUATION OF FUTURE DISCHARGES (Session 2, Part 2)

Production and emission of tritium from nuclear facilities, and the resulting problems (IAEA-SM-232/12)
H. Bonka
[Federal Republic of Germany]

An analysis of tritium releases to the atmosphere by a controlled thermonuclear reactor (IAEA-SM-232/51)
T.J. Bander, D.S. Renne, W.F. Sandusky
[United States (PNL)]

Laser fusion: Status, future and tritium control (IAEA-SM-232/102)
P.E. Coyle
[United States (Lawrence-Livermore)]

(a) In collaboration with the Nuclear Energy Agency of the Organization for Economic Cooperation (Paris); NEA (1980).

MEASUREMENT OF TRITIUM (Session 3, Part 1)

HT-HTO Sampling at the Nevada Test Site (IAEA-SM-232/87)

R.J. Straight
[United States (REECO)]

A low-background liquid scintillation counter for measuring low-level tritium (IAEA-SM-232/32)

T. Iwakura, Y. Kasida, Y. Inoue, N. Tokunaga
[Japan]

A rapid and quantitative method to determine the tritium content in DNA from small tissue samples (IAEA-SM-232/7)

V. Kasche, R. Zöllner, H. Amneus, L. Näslund
[Federal Republic of Germany and Sweden]

TRITIUM IN THE AQUATIC ENVIRONMENT (Session 3, Part 2, Session 4 and Session 5, Part 1)

Transfer and incorporation of tritium in aquatic organisms (IAEA-SM-232/96)

R. Kirchmann, S. Bonotto, S.D. Soman, T.M. Krishnamoorthy, T.S. Iyengar, A.A. Moghissi
[Belgium, India, United States]

Microbial activity measurements by means of tritium-labelled substrates (IAEA-SM-232/5)

H-G. Hoppe
[Federal Republic of Germany]

Incorporation of tritium into planctonic algae in a continuous culture under dynamic conditions (IAEA-SM-232/40)

S. Strack, G. Kistner, C.C. Emeis
[Federal Republic of Germany]

Tritium behavior in aquatic plants and animals in a freshwater marsh ecosystem (IAEA-SM-232/50)

L.W. Adams, T.J. Peterle, G.C. White
[United States (Ohio State)]

Distribution of tritium in a chronically contaminated lake (IAEA-SM-232/74)

B.G. Blaylock, M.L. Frank
[United States (Oak Ridge)]

Monitoring for the dispersion of discharged tritium in sea-water around the Tokai-mura fuel reprocessing plant (IAEA-SM-232/27)

T. Nomura, Y. Kishimoto, A. Hirayama, S. Fukuda, K. Iwasaki
[Japan]

Tritium in the Savannah River estuary and adjacent marine waters (IAEA-SM-232/80)

D.W. Hayes
[United States (Savannah River Laboratory)]

An assessment of the radiological impact of tritium released to sea from the Windscale fuel element reprocessing plant (IAEA-SM-232/10)

J.A. Hetherington, J.C. Robson
[United Kingdom]

Oceanic distribution and transport of tritium (IAEA-SM-232/67)

H.G. Ostlund, R.A. Fine
[United States (Miami)]

Tritium in the North Atlantic Ocean: Inventory, input and transfer into deep water
(IAEA-SM-232/98)
W. Weiss, W. Roether, E. Dreisigacker
[Federal Republic of Germany]

TRITIUM IN THE TERRESTRIAL ENVIRONMENT (Session 5, Part 2, and Sessions 6 and 7)

Transfer and uptake mechanism of tritium in soil (IAEA-SM-232/95)
J.K. Miettinen
[Finland]

Transfer of tritiated water vapour to and from land surfaces (IAEA-SM-232/3)
J.A. Garland
[United Kingdom]

Environmental transport and cycling of tritium in the vicinity of atmospheric releases
(IAEA-SM-232/80)
C.E. Murphy, Jr., M.M. Pendergast
[United States (Savannah River Laboratory)]

Influence of the rate of conversion of HT to HTO on projected radiation doses from
release of molecular tritium (IAEA-SM-232/81)
D.G. Jacobs, C.E. Easterly, J.E. Phillips
[United States (Oak Ridge)]

Behaviour of tritium in the plant domain (IAEA-SM-232/100)
T.M. Krishnamoorthy, T.S. Iyengar, S.D. Soman, G. Solis de Bravo, J.R. Ortiz Magana,
C. Archundia, L.L. Martinez de Alva, R.M. de Nulman, N.B. Juan, A. Yuthamanop
[India, Mexico, Phillipines, Thailand]

Environmental tritium in trees (IAEA-SM-232/44)
R.M. Brown
[Canada]

Transfert à la ration alimentaire du tritium émis par les installations nucléaires
(IAEA-SM-232/99)
P. Bovard, J. Delmas, Y. Belot, H. Camus, A. Grauby, R. Kirchmann, J. Van den Hoek
[France]

Transfer and incorporation of tritium in mammals (IAEA-SM-232/48)
J. Van den Hoek, R. Kirchmann, N.B. Juan
[The Netherlands, Belgium, Phillipines]

Transfer of tritium to foetuses and newborns from mother mice administered with
tritiated water (IAEA-SM-232/34)
Y. Ueno, S. Nakamura, T. Takahashi, H. Aiba
[Japan]

Métabolisme de molécules tritiées, chez le rat: Etude sous l'angle de la radioprotection
(IAEA-SM-232/39)
L. Jeanmaire, Y. Vernois
[France]

Radiation dosimetry in experimental animals exposed to tritiated water under different
conditions (IAEA-SM-232/78)
R.B. Cumming, G.A. Sega, M.F. Walton
[United States (Oak Ridge)]

Tritium distribution and incorporation from tritiated water or tritiated precursors of DNA, RNA or proteins (IAEA-SM-232/63)

D.J. Mewissen, M.E. Furedi, A.S. Ugarte, J.H. Rust
[United States (Chicago)]

Induction of specific locus mutations in the mouse by tritiated water (IAEA-SM-232/85)

W.L. Russel, R.B. Cumming, E.M. Kelly, E.L. Phipps
[United States (Oak Ridge)]

TRITIUM IN MAN (Session 8 and Session 9, Part 1)

Biological half-life of tritium in humans (IAEA-SM-232/65)

A.A. Moghissi
[United States (EPA)]

Diffusion kinetics of tritiated water through human skin (IAEA-SM-232/43)

R.V. Osborne
[Canada]

Models for assessing the environmental exposure by tritium released from nuclear installations (IAEA-SM-232/15)

K.J. Vogt
[Federal Republic of Germany]

Environmental transport and long-term exposure for tritium released in the biosphere (IAEA-SM-232/47)

R. Bergman, U. Bergstrom, S. Evans
[Sweden]

Methodology for hazard assessment of environmental tritium (IAEA-SM-232/4)

J. Gruber, A.A. Moghissi
[Berlin (West) and United States (EPA)]

Tritium distribution in man and his environment (IAEA-SM-232/75)

D.C. Bogen, G.A. Welford, C.G. White
[United States (HASL)]

World-wide population doses from tritium released from nuclear facilities (IAEA-SM-232/69)

J.K. Soldat, D.A. Baker
[United States (PNL)]

Tritium in the environment - NCRP Report No. 62 (IAEA-SM-232/101)

M. Eisenbud, B. Bennett, R.E. Blanco, E.L. Compere, E. Goldberg, D.G. Jacobs, J. Koranda, A.A. Moghissi, J. Rust, J.K. Soldat
[United States (NCRP)]

MONITORING OF TRITIUM (Session 9, Part 2, and Session 10)

Impact on the environment of tritium releases from the Karlsruhe Nuclear Research Center (IAEA-SM-232/2)

L.A. König
[Federal Republic of Germany]

Monitoring experiences with tritium in JAERI (IAEA-SM-232/30)

Y. Yoshida, A. Yabe, M. Kishida
[Japan]

Environmental aspects of tritium from CANDU station releases (IAEA-SM-232/49)

D.J. Gorman, K.Y. Wong
[Canada]

Tritium monitoring at the Sandia Tritium Research Laboratory (IAEA-SM-232/56)

T.K. Devlin

[United States (Sandia of California)]

Transport through a trench cover of gaseous tritiated compounds from buried radioactive wastes (IAEA-SM-232/60)

A.H. Lu, J.M. Matuszek

[United States (New York State Department of Health)]

Fifteen years of experience in handling tritium problems in connection with low-energy particle accelerators (IAEA-SM-232/8)

P.F. Sauermann, W. Friedrich, J. Knieper, H. Printz

[Federal Republic of Germany]

List of Chairmen of Sessions and Secretariat of the Symposium

List of Participants

Author Index

Note 6—Members of the Expert Group of the Nuclear Energy Agency of the Organization for Economic Cooperation and Development

Dr. W.D. Rowe (Chairman)	United States
Dr. D. Beninson	UNSCEAR (up to December 1978)
Dr. H. Bonka	Federal Republic of Germany
Miss P.M. Bryant	United Kingdom
Mr. R. Coulon	France
Mr. D.L.M. Hunt	United Kingdom
Prof. Dr. B. Lindell	Sweden
Dr. R.V. Osborne	Canada
Mr. H.T. Peterson, Jr.	United States
Dr. G.R. Plumb	United Kingdom
Mr. A.C.B. Richardson	United States
Mr. B. Berkerk	The Netherlands

Consultants

Dr. D.T. Pence	United States
Mr. J. Pomarola	France

Editor

Dr. R.V. Osborne	Canada
------------------	--------

Secrétariat

Dr. B. Rüegger	NEA
----------------	-----

Capsule Chronology

- July 1945** Trinity Test—Alamogordo, New Mexico. Possibility of fallout contamination considered and measurements made. Monitoring of area and local inhabitants continues for several months (UCLA and Berkeley).^(a) Cattle receive beta burns, and some go to Oak Ridge after a few months.
- August 1945** Photographic film at Eastman Kodak Company fogged from contamination of packaging materials that incorporated fallout from Trinity. Not published until 1949 (Webb, Eastman Kodak Co. at Rochester).
Hiroshima and Nagasaki bombs: Fallout plays only a small role because bursts were high. However, contamination reported many years later.
- June–July 1946** Operation Crossroads at Bikini. Underwater shot (Test Baker) provides graphic demonstration of possible dimensions of fallout contamination of ships, personnel, and environment. Work continues for several months. Potential appreciated for contamination of marine biota, including organisms attached to the hulls of ships.
- 1947** Resurvey of Bikini begins (Donaldson et al., University of Washington; U.S. Navy; Hopkins Marine Station; Scripps Institution of Oceanography; Oak Ridge; others).
Idea of Pacific Proving Grounds gains.
UCLA Atomic Energy Project organized. Takes active role in tests and fallout measurements for decades thereafter (Warren, Larson, Romney et al.).
Results of animal exposures at Operation Crossroads published (Tullis and Warren, Harvard; Navy).
- 1948** Sandstone Tests in Enewetak area. Follow-up shows tumors in plants.
Further follow-up of Bikini contamination and effects.
Follow-up of contamination at Trinity Site (Bellamy, Larson et al., UCLA) started in summer 1947. Area of fallout found to be much larger than 1945 measurements indicated.
- 1949** Fogging of photographic film at Eastman Kodak from Trinity Fallout published.
President Truman announces that Russia has exploded a nuclear device.
- 1950** Nevada site designated to meet needs for test site in continental United States. Site for 582 announced shots, plus many unannounced. About 100 of the total were in the atmosphere.
- 1950s** Continuing studies of marine and terrestrial biota at Pacific Proving Grounds. Continued intermittently through present.
- 1951** Greenhouse test series in Pacific; animals exposed.
First tests at Nevada Test Site (NTS)—Operation Ranger.
Radioactive snows detected in several cities.
More resurvey of Trinity site (Larson et al., UCLA).
Contamination of biota on NTS first described (UCLA).

(a) For abbreviations and acronyms, see Appendix D.

- 1951 Sunshine Project and unit developed by Willard Libby.
- 1952 Ivy series in the Pacific. Mike shot, one of the first thermonuclear devices raises potential for contamination from fallout by a large factor.
Tumbler-Snapper series at NTS.
- 1953 Airborne radioactive materials from three NTS shots (Snapper) characterized (Olafson et al., UCLA)
Eisenbud spearheads fallout collection network using sticky paper and air sampling. Publishes a summary of findings.
Sheep exposures occur in Nevada-Utah; deaths blamed on NTS tests.
Comparative study of Hanford and Utah range sheep (Bustad et al., Hanford).
Permanent laboratory for biology established in the Pacific islands. Used especially by University of Washington and AEC New York Operations office people.
First reports of PHS participation in offsite monitoring at NTS. Also PHS air sampling network established.
Upshot-Knothole series at NTS.
- 1954 Castle series in Pacific. Shot Bravo makes fallout a worldwide concern. Contamination of Marshall Islands and the Marshallese and of a Japanese fishing boat triggers enormous responses. These include over three decades of study and medical care of the exposed Marshall Islanders (Conard, Cronkite, et al., Brookhaven; also personnel from NRDL; Naval Medical Center; Walter Reed Hospital; others).
Lucky Dragon arrives at home port (March 17) with twenty-two sick fishermen. Causes uproar in Japan, with much concern for contamination of seafood as well as health of fishermen. Much good scientific detective work by Japanese on what occurred. High-level conferences for balance of year.
The Lucky Dragon and Marshallese incidents constitute a watershed in general attitudes toward the potentials of fallout.
Iodine first reported in cattle thyroids at market in the United States. Report of high levels of radioactivity in rain at Troy, New York.
- 1954-1956 Expeditions mounted to check seawater and seafood contamination in Pacific, particularly the western Pacific.
- 1955 Congressional hearings on fallout. Documentation of global fallout levels.
Teapot series at NTS.
Radioactivity measurements made part of Water Quality Control network.
- Mid-1950s Role of food chains in transfer of fallout radionuclides becomes very evident, especially for iodine and strontium.
- 1956 Redwing series in the Pacific.
Sunshine Project data made available by Libby publications; followed by others.
Lawsuit filed by sheep ranchers.

- 1956** Reviews published of medical care of Marshall Islanders.
 NAS-NRC reports on Biological Effects of Atomic Radiation (BEAR).
 British Medical Research Council report on same subject. Both concentrate on fallout. NAS-NRC series continues in later years.
 Strontium content of human bone and of stillborns, calf and sheep bones given by Libby.
 Los Alamos does survey of cesium in milk.
- 1957** More Congressional hearings on nature of fallout; standards and the "worry dose" considered.
 Unclassified report documents events of Shot Bravo (Dunning, AEC). Eisenbud and Libby present series on global fallout.
 Safety criteria explained.
 Repatriated populations on some of the Marshall Islands begin to show mounting body contents of radioactivity, apparently from food.
 Plumbbob series at NTS.
 Comar's work on thyroid contamination from fallout.
 USPHS report on iodine in thyroids of small animals (Wolff).
 Reports on fallout in man from Lamont group (Kulp, Columbia University).
- 1958** Hardtack, Phase I series at Pacific Proving Grounds, Phase II at NTS.
 Publication of estimates of radiation exposures from Nevada Test Site (Dunning, AEC).
 Los Alamos summarizes hazards of worldwide fallout (Langham and Anderson).
 Fallout discussions become more and more wide-ranging and strident.
 Further oceanic surveys, as part of Operation Hardtack, Phase I.
 United Nations Scientific Committee on Effects of Atomic Radiation (UNSCEAR) begins periodic review of all radiation sources, but concentrates on fallout radionuclides.
 Hazard from ^{14}C evaluated (Totter et al., AEC; Pauling, Cal. Tech.).
 Summaries of cesium in the biosphere by Langham and Anderson (Los Alamos).
 Moratorium on nuclear testing declared in November; ends September 1961.
- 1959** Lawrence's book on Trinity.
 NTS changes to underground testing; a few release radioactivity offsite.
 Consumers Union samples teenagers' diets.
- 1960** Summary characterization of fallout at NTS after a decade of testing (Larson and Neel, UCLA).
- 1960 et seq.** Federal Radiation Council (FRC) sets out basic radiation protection guides for population as well as workers, also protective action guides for use when intake period is short. Much attention to fallout problems, especially strontium and iodine. Reports of NAS-NRC advisory committees to FRC.

- 1960 et seq.** Biota surveys continue at Pacific atolls: Lawrence Livermore Laboratory (LLL) added to those named earlier.
Special problems of arctic food chains uncovered (see chapter 15).
Tri-City Study under way. Analyses of food in New York, Chicago, and San Francisco for fallout radionuclides.
- 1961** Bibliography of world's literature on radioactive fallout (Bost et al., AEC).
- 1961-1967** USPHS institutional diet sampling program for fallout radionuclides.
- 1961-1969** FDA sampling of whole diet for fallout radionuclides.
- 1962** More Congressional hearings on fallout problems.
Utah studies of iodine in fallout, milk, and people reach most active stage (Pendleton, Lloyd, Mays).
Offsite monitoring by PHS described in detail.
- 1963-1967** Connecticut State Department of Health sampling of representative diet of 18-year olds.
- 1963** Congressional hearings on Fallout, Radiation Standards and Counter-measures. Includes many estimates of radiation dose from global and local fallout.
The Knapp study on iodine in milk. More in hearings.
Further measurements of seafood contamination in the Pacific (Seymour, University of Washington; Lowman, Puerto Rico).
PHS plans study of thyroid and bone cancer, leukemia, and congenital malformations in southwestern Utah.
Limited Test Ban Treaty.
- 1964** Radioactive particles from fallout identified in lung tissue at autopsy (Wegst, Pelletier, and Whipple, University of Michigan).
PHS work on iodine in bovine thyroids.
FRC work on milk.
- 1964-1967** California State Department of Public Health sampling of house diets of hospitals for fallout radionuclides.
- 1965** Concepts of critical nuclides, critical pathways, and critical population groups suggested by ICRP (more in chapter 15).
PHS on ¹³¹I in children's thyroids.
Weiss's (PHS) paper on leukemia mortality in southwestern Utah.
- 1969** Thyroid nodules described in Marshall Islanders.
Series of reports by Sternglass linking infant mortality to fallout from nuclear weapons tests; summarized in his 1972 book. Causes much discussion and reanalysis of data over several years. Discussed by Tomkins and Brown (PHS) and Tamplin (LLL) in 1969.
FAO-IAEA-WHO Symposium on Environmental Contamination by Radioactive Materials. Emphasizes agricultural problems (see chapters 11 and 15).
Further work on arctic food chains (more in chapter 15).

- 1970** Baneberry event at NTS (venting of underground test shot). Much study locally and in Utah.
Nonproliferation treaty (March).
- 1971** Thyroid nodularity studied in school children of southwestern Utah (USPHS).
Report of Utah measurements subsequent to Baneberry event (Pendleton et al., University of Utah).
PHS (BRH) reports on search for thyroid abnormalities in "exposed" groups of Utah and Nevada versus "unexposed" group in Arizona. Studies begun in 1965.
- 1973** Report by Congress of Micronesia regarding contamination of Marshall Islands and the problems raised thereby.
Dose estimates from marine food chain at Enewetak (Robison, Koranda, LLL). Also evaluation of transuranics (several laboratories).
- 1974** Recommendations of AEC Task Group for Clean-up and Rehabilitation of Enewetak Atoll.
Publication of medical findings in Utah children.
Further PHS clinical studies in Utah and Nevada.
- 1975** Twenty-year report on Japanese fishermen (Kumatori).
- 1975-1976** Twenty-seven and twenty-eight year resurveys of Trinity site (Hakanson and Johnson et al., Los Alamos).
- 1975 et seq.** Much work using whole-body counters for measurement of body content of fallout radionuclides in general population.
- 1977** PHS Center for Disease Control finds "cluster" of leukemia cases in military participants in certain Nevada tests, e.g., Shot Smoky in Plumb-bob series. Called "Atomic Veterans." Defense Nuclear Agency begins review.
Dose commitment from fallout estimated by UNSCEAR. Also tritium inventory.
- 1978** Report of fallout contamination in inhabitants of Nagasaki suburb. Search for effects negative (Okajima, Nagasaki University, and ABCC).
Preventive and Emergency Action Guides for Population Exposure suggested by FDA.
- 1979** Lyon et al. propose that Nevada tests increased leukemia incidence in Utah. Use low- versus high-fallout counties over previous fifteen years. Much discussion follows. Problems in study pointed out by Land (National Cancer Institute) and Enstrom (UCLA).
Books prepared for Marshallese (Bair, Healy, Wachholz, et al.).
- 1980s** Offsite Radiation Exposure Review Project and Dose Assessment Advisory Group operated by DOE at Nevada Operations Office.
- 1980** Dietary radioactivity study of Marshall Islands indicates persistent contamination of local foods.
More on resettlement of Bikini people (Clusen, DOE).
Brookhaven begins to concentrate on reevaluating dosimetry, especially thyroid, in the Marshall Islands.

- 1980** Review of dose assessments from fallout from Nevada tests.
Comprehensive survey of comparative plutonium distribution at Trinity and Los Alamos (Hakanson and Nyhan).
Probability-of-occurrence approach to cancer risk from radiation exposure (Bond, Brookhaven).
- 1981** Radiation Exposure Compensation Act.
Feasibility study for epidemiologic investigation of populations of Nevada, Utah, and Arizona (Hoffman et al., BRH).
Approach to reconstruction of doses from fallout by measuring radioactivity of samples of bricks (Wrenn, University of Utah). Also suggests level of iodine be measured in old samples of thyroids removed in hospitals by determining long-lived iodine in paraffin blocks from pathology laboratories.
- 1982** New estimates of risk of resettling Bikini (Kohn and Dryer).
Scientists implicated in sheep cases.
- 1983** Announced that U.K. will study health effects of nuclear tests.
Report on soil sampling programs for residual ^{137}Cs and ^{239}Pu in parts of Nevada and Utah (Environmental Measurements Laboratory, DOE).
Book and Goldman publish overview of research during era of nuclear weapons testing (UC, Davis).
Final report on organ doses from radionuclide intake by Nuclear Test Personnel (Lee et al., Advanced Research and Applications, Inc.).
- 1984** Judge in Salt Lake City rules that fallout caused certain cases of cancer in exposed population.
More on childhood leukemia and fallout—negative results (Land et al., National Cancer Institute).
- 1986** Final appeal denied in sheep case.
- 1987** First volume of Hacker's review of radiation safety in the MED and at the tests published.

Chapter 12

New Dimension Number Three— Fallout From Nuclear Weapons Tests

Overview

This chapter reviews the biomedical aspects of the most pervasive and unsettling of the three "New Dimensions" brought upon the scientific and technical biocommunity by the advent of atomic energy. This, the latest of the new dimensions, involved both individual organisms and the entire biosphere. It spilled over into the sociopolitical arena and generated one of the most serious confrontations between science and society since the controversy over evolution, perhaps since the industrial revolution.

The chapter is organized chronologically within the major theatres of operation and technological problems. We begin with the very first nuclear weapons test, the Trinity shot at Alamogordo, New Mexico. We show that, contrary to much that has been said, the possibility of radioactive fallout was considered seriously. We consider the bombings of Hiroshima and Nagasaki, where fallout potential received relatively little attention, and then go to the first major test series, "Operation Crossroads," held at Bikini Atoll in the central Pacific Ocean. It is emphasized that this series, particularly the underwater shot, drove home the potential for serious, in fact lethal, contamination of a naval task force by radionuclides from fallout.

A major section is devoted to the tests at the Pacific Proving Grounds beginning with the resurvey of Bikini and progressing through the subsequent fission weapon shots to the thermonuclear weapon detonations. The "Bravo" shot of Operation Castle receives the attention it deserves as the first event to produce major contamination of a large area and to contaminate significant human populations. We follow the biomedical research and clinical findings in the residents of the Marshall Islands, the occupants of the Japanese fishing boat that received fallout in quantity because of an unpredictable shift in winds at high altitudes, and some of the sociological and psychological overtones of these events. We describe, largely by reference to the work by the University of Washington Fisheries Laboratory and collaborating groups, the surveys of the Marshall Islands for residual contamination and the movement of radionuclides in the ocean. We also review in some detail the several oceanographic expeditions mounted by Japanese and American investigators and organizations and

the knowledge they gained regarding movement of radioisotopes in the marine environment, possible effects on aquatic biota, and the possible contamination of food from the sea.

To introduce the study of fallout behavior and effects in terrestrial environments, we look first at the well-designed and informative resurvey of the Trinity site. We turn next to nuclear weapons testing in the continental United States at the Nevada Test Site. The early experiences in mapping fallout and early biological information from the Nevada Test Site set the stage. The most extensive discussion concerns offsite contamination from the Nevada tests. It proceeds from the first realizations that such contamination was occurring through the sudden appreciation of the role of food chains in bringing contamination to man, through clinical studies of the populations to the final stage, litigation. The saga of the large sheep herds is also considered, plus the onsite exposures of military personnel involved in training exercises ("Atomic Veterans") and onsite workers.

The summation of the fallout from the Nevada tests and the injection into and slow release from the stratosphere of radionuclides from the Pacific shots into the entity we call "global fallout" is discussed next. It is necessary to devote considerable attention to the physical events and measurements, to the somewhat unorthodox dosimetry introduced by the Sunshine Project, and to correlative federal and international programs. The biomedical aspects of global fallout are described by considering the radionuclide content of important biological materials and the large questions of contamination of food and water, discrimination factors, and protective actions.

Although details of protection standards for radionuclide exposure are contained in chapter 16, the application of these to environmental contamination, particularly to radionuclides from fallout, was considered to require specific attention in this chapter. Thus, there is a section devoted to radiation protection standards from fallout. Emphasis is placed on the development of exposure standards for populations, the identification of special problems, and the development of both radiation protection guides and protective action guides by the Federal Radiation Council.

The chapter concludes with a recitation of some of the principal dilemmas and problems of the fallout experience. It includes the question, "Should we have tested?"; the role of the hidden doses (i.e., doses from fallout radionuclides not included in the usual routine measurement of external radiation); and an exposition of the crusade of Ernest Sternglass on fetal and infant mortality that began around possible effects of fallout. Finally, there is a short review showing that, despite the myriad problems introduced by the fallout situation, it was responsible for some significant progress in the fields of biology and medicine. This will be more apparent in chapter 13. Because of the enormous amount of work done and the voluminous publications on fallout problems, the chapter is devoted primarily to work done by U. S. investigators. However, from time to time the contributions of investigators and organizations in other countries are introduced. Sometimes these are described as part of an ongoing discussion, sometimes under a separate heading.

I. Introduction

In chapter 6, we met "New Dimension Number One—The Fission Products" and in chapter 7, "New Dimension Number Two—Plutonium and the Transplutonic Elements (The Actinides)." The first was a new dimension by virtue of the

addition of hundreds of new isotopes of elements already known for the most part as stable rather than radioactive elements. The second posed a new dimension by introducing a whole new family of manmade elements whose biological behavior and effects had to be ascertained. These were new dimensions primarily to science and technology. The third new dimension, "Fallout from Nuclear Weapons Testing," the subject of this chapter, added not only new scientific and technical problems but problems of the first magnitude in the political and military arenas. The gradual perception of these problems and what they were is the subject of this chapter.

Over the thirty-year period beginning in 1945, more than 800 tests of nuclear "devices" were carried out by the six nuclear powers. The announced totals are: United States 579, USSR 136, United Kingdom 26, France 43, People's Republic of China 16, and India 1. The majority of the tests centered on weapons development. However, a few were directed toward the uses of nuclear explosives for peaceful purposes, such as digging harbors and canals and related applications. (Details are in chapter 14.) The total energy yield in kilotons (kt) of TNT equivalent was over 325,000, divided roughly as follows: United States 77,500 kt, USSR 207,000 kt, United Kingdom 18,200 kt, France 7,000 kt, People's Republic of China 15,500 kt, and India 13 kt. Obviously, the United States carried out a much larger number of relatively small tests than some other countries. Indeed, some U.S. tests were very small indeed.^(a)

Because it was testing in the atmosphere that contributed the most to fallout, it should be remarked that, of the total yield of 325,000 kt, approximately 270,000 kt (370 tests) were in the atmosphere. Second in significance to the understanding of the importance of fallout problems were the underwater tests, even though there were only six of these, with a total yield of 90 kt. The later underground shots are not included in this summary.

Details on the statistics described above can be found in a review by Carter and Moghissi (1977) with a commentary by Richmond (1978) and in U.S. government publications (e.g., NVO 1982).^(b)

We saw in chapter 6 that the fission products consist of a complex mixture of radionuclides whose radioactivity decreases rapidly with time. There are many isotopes present with very short half-lives and many products that are themselves the progenitors of a chain of daughter products. Also, some are gases initially but become solids on decay to a subsequent degradation product. As discussed briefly in chapter 6, such a complex mixture of substances, each decaying exponentially with time, presents a composite decay curve that can be

(a) Remember that the bombs that devastated Hiroshima and Nagasaki were nominally about 20 kt. Also note that these figures do not include relatively recent tests.

(b) Thanks are due especially to Gordon Facer, Bruce Church, Marshall Page, Jr., and colleagues for making these available, relatively soon after declassification in some instances. The location of the several test sites, code names with dates, and a few characteristics for all of the announced tests to date of publication of the United States, the United Kingdom, and France, and the dates for Soviet, Chinese, and Indian tests are also given by Carter and Moghissi and in the U.S. government report cited. Much greater detail was made available to me through the Division of Military Applications of the Department of Energy (DOE) and the document center at Las Vegas, Nevada. These include the paths of the fallout, radiation dose contours as a function of time and distance, and much else that cannot be described except in general terms in a book with so broad a mission as this one.

represented as a power function of time, e.g., most characteristically as $(\text{time})^{-1.2}$. The exponent may vary from -1.1 to -1.4 depending upon the exact construction of the device.

The predominant early radiations are beta particles and gamma rays. Thus, the chief early biological hazard from fresh fission products is usually external radiation.^(a) Hazards from internally deposited fission products arise somewhat later.

Fallout from weapons tests consists primarily of these fission products, plus from enormous to small amounts of dust and debris depending upon the altitude and conditions of the burst. (Obviously, a surface or near-surface burst will entrain much more of these than a high-altitude detonation.) In addition, gravimetrically small but biologically significant quantities of unfissioned alpha-particle emitters from the device and relatively large amounts of radioelements produced by neutron activation of elements in the device and in the environment will be present. In the case of the fission-fusion devices (the "hydrogen bomb"), quantities of tritium and other products special to this process will also be included.

In chapter 6, we referred to Glasstone's *Sourcebook on Atomic Energy* among others for details on the formation of fission products and their characteristics. For their behavior in fallout from nuclear weapons, the standard reference is Glasstone's *The Effects of Nuclear Weapons*. This has gone through three editions, the most recent of which is Glasstone and Dolon (1977). Therein can be found detailed expositions of the major components of a nuclear explosion, i.e., blast, heat, and radiation; the patterns of fallout, both local and global;^(b) how to calculate the external dose at any given time as well as the dose to infinite time; and much more. Many other sources are, of course, available, including short summaries in numerous texts, the monographs cited in chapter 11, and exhaustive discussions in the many Congressional hearings called as the dimensions of the problems of fallout became more and more apparent (U.S. Congress 1955, 1957, 1959, 1962, and 1963). A very useful review of research around the problems of fallout was prepared recently by Book and Goldman (1983) for the Department of Energy. This provides a check-back system for the major enterprises.

Let it be emphasized that the composition of and problems from initial fallout from weapons are quite different from those that might be encountered in releases from a nuclear reactor (see earlier chapters). It is only after a period of aging of the fission products that the characteristics and problems begin to approach each other. The external radiation dose predominates in the early

(a) The devices also produce neutrons that add to the external dose, but these do not arise from the fission products themselves. Inhalation of iodine isotopes can also be an early hazard.

(b) Glasstone and Dolon describe the three major classes of fallout (local, tropospheric, and stratospheric) in detail. The organization of this chapter is somewhat around these classes in that most of the earlier problems were local with a small component of tropospheric transport, e.g., Trinity, Hiroshima, Nagasaki, Crossroads. The Nevada Test Site experience, on the other hand, had a much larger component of tropospheric contamination, and the major Pacific tests had a large component of stratospheric contamination and transport.

phases of fallout even more than with reactor fission products, a fact that underlies some of the apparent neglect of internal doses in considering weapons fallout that has become a source of recent concern.

With the cessation of atmospheric testing and the substitution of tests deep underground, the furor of the 1950s and 1960s died down, and only the specter of nuclear war kept the fallout issue alive.^(a) However, the recent development of litigations concerning possible effects of the fallout from atmospheric testing on populations in the continental United States, including the "Atomic Veterans" (U.S. Congress 1980) and the institution of retrospective analyses, have led to a wide-ranging and thorough reopening of the files on the whole story. The U.S. government has established a Coordination and Information Center at the Nevada Operations Office of the Department of Energy in Las Vegas, and thousands of documents are now available, many of which were classified until recently.

There is enough information in these many sources to write a complete book. We will look in this chapter primarily at the historical development of the information and touch lightly at the end on some of the current activities. (The touch will perforce be very light in areas still under litigation.)

The adequacy of the safety measures taken around the tests is at the heart of much of the current polemic. This subject is hardly research, if rigidly defined. Nevertheless, the present compendium would have been forced to enter that arena in some detail were it not for the parallel development of an independent treatise on the safety measures associated with the testing program. Dr. Barton C. Hacker, a historian from the University of Oregon, used interviews, the enormous resources of the Coordination and Information Center, and files of several laboratories to prepare a book, under DOE auspices through the Reynolds Electrical and Engineering Co., Inc. in Las Vegas.^(b) This much expanded and detailed complement to this chapter will trace the various tests almost day-by-day and decision-by-decision. Many of the chapters have been made available to this author already and have provided background for some of the data presented herein. Other descriptions are in the source material cited in chapter 11, especially in the book by Hines (1962).

Let us reiterate that this chapter will concentrate on the tests and the biomedical work done in more or less direct association with them. Later chapters will describe research arising out of the problems produced by the generation of fallout. It should become clear that fallout from nuclear weapons testing provided not only a new dimension for chemistry, physics, biology, and medicine but one of the most significant challenges and boosts that environmental science has ever received. What the physicists and engineers wished to learn and the concomitant development of weaponry are not part of this treatise. Much can be learned from the several biographies and histories cited from time to time (see especially Appendix B).

(a) Along with the continuing survey of the Marshall Islanders to be discussed presently.

(b) The first volume of this compendium was published in 1987 (Hacker 1987). It covers the period of World War II plus Operation Crossroads. This volume (published by the University of California Press, Berkeley, and Los Angeles) is entitled *The Dragon's Tail. Radiation Protection in the Manhattan Project, 1942-1946*.

II. The Story Unfolds

A. Trinity (Alamogordo).

The military aspects of the atomic age burst upon mankind,^(a) for better or worse, at 5:30 a.m. on July 16, 1945 in open desert not far from Alamogordo, New Mexico. This was a test of a plutonium-based device, frequently referred to as "the gadget," atop a 100-ft tower, the climax scientifically and technically of the years of effort expended in the Manhattan Engineer District (MED).^(b) There are hundreds of accounts of that event. A firsthand one written by the ace science reporter from the *New York Times*, William L. Lawrence, is both dramatically readable and basically accurate.^(c) (Lawrence 1959).

As we all know, the results were beyond expectations and filled the observers with awe at the dimensions of what they had done, with pride in the success of their work, and with misgivings for the future unless controls were rigid.

The dimensions of the blast and fireball and the phenomenon of prompt radiation eclipsed, for the casual observer, the more subtle possibilities of fallout. Indeed, not much was heard about fallout from the Trinity shot except in scientific circles until some years after the event.^(d) This has led, in some circles, to the erroneous idea that the MED bomb developers, even the biomedical contingents, were unaware of the potential for more than the prompt radiation release. This was totally untrue, although it is true that only shortly before the test did the calculation of potential fallout reach disturbing magnitudes.

The device was to be detonated close to the ground, and a towering cloud of dust with fission and activation products had to be considered possible. The weather conditions selected for the shot were predicated mostly upon the possible direction such a cloud might travel.^(e)

An extensive monitoring program was set up for Trinity, as part of a broad safety program under the general direction of Louis Hempelmann and the Los Alamos Health Division, with much help from the military. This involved not only intensive work around the site but monitoring offsite and contingency plans for evacuation of the public should the cloud fail to break up as expected or pass over inhabited areas. Hymer Friedell, deputy director of the Medical Division of the MED, had to forego witnessing the test in order to be in a hotel room in Albuquerque ready to communicate to military teams stationed surreptitiously in towns potentially subject to cloud passage to order evacuation if levels at any of them reached alarming proportions.^(f) (See Hacker 1987.)

(a) In a sense, we might say that the atomic age began with the discovery of radioactivity and radium (chapter 1).

(b) A ^{235}U device was ready also but was saved for use in Japan.

(c) Lawrence was the only press writer invited to witness the test. It was considered important that the media be prepared for the planned bombings of Japan if "the gadget" worked. Lawrence was well known to the physicists and was trusted.

(d) It is given proper coverage in Lawrence's book (1959), but that was over a decade later.

(e) The weather conditions for the shot had to take second place to the date for opening of the Potsdam Conference. President Truman wanted to know on or before the day it opened (July 16!) whether or not America had a trump card to play.

(f) Obviously, if evacuation was needed, the real reason could not be given to the residents since security was still very tight. The story would be that an ammunition dump had exploded and there were gas shells in the dump.

Security was still of the essence. Therefore, the level of radiation at which evacuation would be undertaken was chosen to fit only a true emergency pattern. This was much discussed beforehand. Hempelmann and the Los Alamos staff, plus Stafford Warren (see earlier chapters) and advisors from Washington chose a potential calculated integrated dose of 68 roentgens in two weeks as the action level (references are given to original correspondence by Hacker undated). Warren, a practicing radiologist, was reputed to have considered a peak rate of 10 roentgens per hour acceptable if the calculated potential total did not exceed that given above. These are, of course, far beyond any levels that would be tolerated currently for exposure of the public. However these were still wartime conditions. Maintaining the secret forced some compromises with safety, although even today it seems unlikely that any overt short-term effects, certainly no radiation sickness, would have appeared had the peak levels been reached.

Fortunately, no inhabited community of any size received fallout even approaching the level that would have triggered evacuation. Only one area, relatively close to the site, achieved moderately high levels. High readings were found in an area northeast of Bingham, New Mexico, especially along a road running through a steep gorge later nicknamed "Hot Canyon" (Hacker undated). Also, two isolated ranches, not on the maps and not discovered by the military teams before the shot, were discovered in this area. The families on these ranches were monitored carefully. The maximum whole-body accumulated dose for twelve weeks was about 50 roentgens. This was estimated on the basis of readings taken outside of the adobe dwellings and applied really only to one man. The others were indoors most of the time. Evacuation was not considered necessary.

The chief victims of Trinity turned out to be animals and some photographic film. A dog belonging to one of the families above showed clear evidence of beta radiation burns on the paws. Range cattle on a high grassland called Chupadera Mesa turned up with burns on their backs and falling hair that grew back discolored, or, white—not a life-threatening effect but a sufficient loss in market value that the Army bought any cattle the ranchers wanted to sell. It was estimated that about six hundred cattle were affected. About seventy-five were shipped off to Oak Ridge for long-term study and became the basis for the University of Tennessee-Atomic Energy Commission Farm to be described in chapter 13.

Veterinarians confirmed that the lesions in the cattle were classic beta burns and that they had been caused by fallout from the Trinity shot. The fact that no similar effects turned up in the few humans in the Chupadera Mesa area can be attributed to the fact that few were out-of-doors at the time of cloud passage, humans wear clothes, and they bathe. By contrast, the hot particles settling on the coats of the cattle worked down to the underlying skin and remained there. Estimates of the dose to their skin were in the thousands of roentgens. The story of the photographic films came from the Eastman Kodak Company in Rochester, New York and indicates that some fallout had strayed far from the Alamogordo site. During August of 1945, batches of photographic film began to show areas of fogging and spots such as those shown in figure 12.1.

A perceptive physicist named Julian Webb at the Kodak Research Laboratories traced the phenomenon to the black interleaving paper used to separate films in the package. He further traced it to paper made from corn husks from a field in Indiana (Webb 1949). He also deduced that these particles could have

FIGURE 12.1: Eastman Kodak film affected by the fallout from the Trinity Shot, Alamogordo, New Mexico, 1945. The interleaving paper had been contaminated by fallout in Indiana. (Original by Webb [1949]. This copy from Eisenbud [1976] via Kathren.)

reached that cornfield only by transport in air and that some sort of explosion had injected them into the atmosphere. Indeed, he concluded that it was an atomic device—not bad considering the secrecy still pervading the operations, but not unexpected from Julian Webb. He patiently held his counsel and did not publish on the subject until 1949.^(a)

In view of the complete novelty of the experience, the relatively few experienced monitors, and the relative antiquity of both communications and measuring instruments, it was indeed remarkable that anything was learned about the fallout offsite as well as onsite in connection with the Trinity shot.

Back at ground zero, crews in lead-lined tanks were making forays up to, sometimes into the crater and were retrieving samples of a glassy substance that was very highly radioactive (later called “Trinitite”). The residual activity in the crater greatly exceeded expectations partly because the calculations had underestimated the amount of neutron activation that would take place.

No one in an official capacity seems to have been hurt by these very hot samples. However, after things opened up a bit, many adventitious forays by rank and file military were made into the crater to collect souvenir samples (shades

(a) Obviously, Webb was not the only one at Kodak who knew something of the MED. It was Kodak that ran the Tennessee Eastman uranium processing plant at Oak Ridge. Kodak people played an important role in persuading Stafford Warren to leave the University of Rochester to become medical director of the MED, e.g., Dr. Albert Chapman, president of Kodak.

of Becquerel carrying Madame Curie's gift of radium in his vest pocket; see chapter 1). Louis Hempelmann put a stop to that instantly when he learned of it.

In retrospect, two gaps appear in the descriptions of Trinity. There was clearly residual plutonium, since efficiency was not one hundred percent. This should have been present partly in the crater, partly scattered about the environs with the fallout. A full-scale resurvey of the Trinity site was carried out three years later by the group at the University of California, Los Angeles (UCLA), medical school, as will be described in a later section. They did indeed find some plutonium. It was not measured very carefully at shot time, although its presence was hinted at in the initial surveys.

The other gap is the lack of any measures for detection of internally deposited radionuclides, e.g., bioassay, nose swabs, etc. Perhaps bioassay was performed when the individuals returned to their home stations, but such data are not included in the story of safety around Trinity. Obviously, concern focused on immediate hazards, and the monitoring methods were geared to measurements of beta and gamma radiation except for a few alpha counters that were used onsite. The thinking had not yet focused on possible long-term effects.

We must conclude that, despite the overwhelming magnitude of the other aspects, the light, the heat, the blast, fallout both close-in and distant was not neglected in the Trinity operation. Indeed, its potential was highlighted "in house."

B. Hiroshima and Nagasaki

The bombs exploded over the two Japanese cities were detonated at altitudes high enough to entail little entrainment of dust and debris. The immediate problems were largely blast, heat, prompt radiation, and residual radiation caused by neutron activation. Fallout as defined herein was considered a minor component of the events.

Nevertheless, there was some fallout at a distance. Little was said about this until in later years the Japanese pinpointed the areas of highest dose and did a thorough study. Okajima et al. (1978) reported a study done in collaboration with the Atomic Bomb Casualty Commission and the Nagasaki University School of Medicine on individuals, soil, and crops in the Nishiyama area. This area received the highest dose of fallout from the Nagasaki weapon. Whole-body counting and urinalysis for ^{137}Cs showed a significantly greater concentration in the exposed subjects. It was determined by soil and crop analyses that these increased levels were supported by continual ingestion of radiocesium. (The effective half-life of ^{137}Cs is much too short for the amount found in the inhabitants to have been residual from deposition in the body in 1945.) Physical examination and laboratory analyses, including tests for chromosome aberrations, showed no large increase in abnormalities in the exposed compared to the control subjects. Two groups were studied, one in 1969, the other in 1971.

The populations of the two Japanese cities have provided enormously important and useful data on the effects of gamma and neutron radiation in humans exposed at high doses and high dose rates.^(a) However, it is all germane to external radiation and has little pertinence to the mission, and focus of this book, internally deposited radionuclides.

(a) It is a monument to the spirit of all concerned that so much useful information could be gathered from the residuum of tragedy.

C. Operation Crossroads—The Dimensions Expand

In the flush of excitement over the new atomic weaponry and a mixture of a desire to know more about what such weapons might do to a naval task force and a desire to demonstrate the awesome powers involved, "Operation Crossroads" was developed. In contrast to all previous operations and the close security of the Manhattan District, this was almost a public demonstration. A shipload of press correspondents and other observers was present, and numerous dignitaries were invited.

The events took place in June and July of 1946 at Bikini Atoll in the central Pacific Ocean (figure 12.2A and B). It was a joint Army-Navy task force, primarily a Navy show in terms of the targets and operational questions to be solved. It involved 42,000 men and women, 242 target and support ships, and 156 military aircraft (Hacker 1987; Hines 1962, chapter 2), all some 4,500 miles from continental America.

There were two detonations; one an air drop from a B-29 aircraft about five hundred feet above the assembled target vessels^(a) in the tranquil lagoon. The other was an underwater detonation at a depth of about ninety feet below an assemblage of wartime ships. Both had yields approximating those of the Hiroshima and Nagasaki weapons. One objective besides assaying damage to naval ships was an evaluation of the importance or lack of it of contamination from fallout in denying access to and operation of exposed vessels.

"Radiological safety in so huge an undertaking at so remote a site posed massive problems" (Hacker 1987). The MED assumed responsibility, and Stafford Warren headed the Radiological Safety Section. This time, Los Alamos H-Division could not supply all of the manpower needed. All MED labs were asked to contribute manpower and equipment for monitoring and maintenance of safety.^(b) Some friendly, and some not-so-friendly competition developed among the labs as they began to gather their equipment for the operation. This was, to a degree, the first time the labs had worked shoulder to shoulder and had theoretically to trust the instrumentation developed by others (Andrews 1980). However, the organization was tightly military, and such problems were handled by fiat.

The radiation safety aspects are being described in depth by Hacker and will not be expanded upon here except to comment that it was ruled that workers should not have total exposures over 50 to 60 roentgens in two weeks or more than 10 roentgens in one day.

On the biomedical research side, there were several projects. The University of Washington group studied aquatic biology of the region pre-shot and gathered a variety of samples post-shot. Test animals were placed on over twenty vessels for Test Able at various distances from ground zero.^(c) These were retrieved in two days post-shot. There were 200 pigs, 60 guinea pigs, 204 goats, 5,000 rats, and 200 mice (Hines 1962, p. 35). Good laboratory facilities were afforded by the hospital ship, USS *Haven*, which became a focus for the biomedical program.

The air drop test (Test Able) contributed more to the understanding of acute radiation effects than to those of fallout. The underwater test (Test Baker) produced the first full realization of how much contamination could be produced

(a) Unfortunately, somewhat to the side of the intended ground zero.

(b) Chicago, Oak Ridge, and Rochester contributed many individuals.

(c) The test animals were under the supervision of Captain R. H. Draeger, USN, from the Naval Medical Research Institute in Bethesda, Maryland.

by a nuclear bomb burst in sea water. Not only did the waters of the lagoon become highly radioactive, but tons of heavily contaminated water thundered onto the target fleet from the 2,200-ft diameter column of water. Much of the radioactivity became fixed to the metal. Even ships that did not receive contaminated water showered from above became contaminated by a radioactive mist from the base surge.

The early drone planes that entered the area for radiation readings after Test Baker reported levels of activity of such high intensity that no human could enter for more than a few minutes. Surface patrol boats soon had to turn back also. The activity levels were far above predictions. Salvage efforts were slowed or abandoned, and ships that might otherwise have been saved were flooded. It was three days before radiation levels in the lagoon had decreased to the point where salvage efforts and recovery of instruments and animals could begin in earnest. For Test Baker, there were twenty pigs and two hundred rats on four ships. Mortality was high, partly because of the longer exposure times and higher doses resulting from the delays in retrieval.

Contamination spread to vessels not in the target array. If they entered the more radioactive lagoon water, the activity attached itself by strong chemical bonds to the metal and also was taken up avidly by the ever-present barnacles^(a) on the hulls. Thus, being below decks did not necessarily afford protection. Many of the ships had to be towed from the anchorage, not because of structural damage, but because they were too radioactive to permit crews to board and operate them.

The first tows were to Kwajalein, which had to become the new base for operations because of the persistent radioactivity in Bikini Lagoon. Eventually all ships involved that did not sink or have to be beached received decontamination, but the results were disappointing. The techniques required were much more than a simple hosing down. From this eventuated the Naval Radiological Defense Laboratory (NRDL) on Hunters Point in San Francisco Bay, since that area became a repository for many of the Bikini vessels. (See chapter 13 for details.)^(b)

(a) The term "barnacles" is used loosely as a generic term for the many organisms that attach to hulls of ships. A more accurate term might be "fouling organisms" because they may or may not have been true barnacles in this instance. However, most landlubbers call all such organisms attached to ships "barnacles" and that is why it is used here.

(b) During the interval between the Baker experience and full functioning of the Naval Radiological Defense Laboratory, the Armed Services, particularly the Navy, mounted an intensive training and education program. Only a small number of competent lecturers were available for such a program. Among them was H. L. Andrews of the U. S. Public Health Service. He appears to have spent many months almost full time in elementary shipboard training and then intensive courses at the main Navy building and elsewhere in Washington (Andrews 1985). This was coordinated by the Armed Forces Special Weapons Project. Interestingly, the notes and syllabus from these courses developed by Andrews with help from Ralph Lapp formed the basis for the highly successful text, *Nuclear Radiation Physics* by Lapp and Andrews used very widely for decades. Obviously, while facilities for attacking the problems experimentally were being readied, the word was being spread, mostly under tight security restrictions. The burden of specific training in the new field remained in the hands of the Armed Forces for many years. A further insight into the training efforts of the Armed Services during this period of hiatus in other quarters can be found in the transcript of a television interview between H. L. Andrews and L. S. Taylor, done in August, 1978. The entire series has been published recently by the Food and Drug Administration (Taylor and Sauer 1984). Dr. Andrews' remarks appear on page 5.

Not much can be said about the animals aboard the target ships for each test. They were necropsied in laboratories aboard the *Haven* or saved for observation. Acute radiation syndrome was probably all they found. Many were already dead. A description of the necropsy findings is given by Tullis and Warren (1947). The lesions were typical of high-dose ionizing radiation.

By contrast, the radiobiological survey team under the leadership of Lauren Donaldson (University of Washington) could get specimens of sea life from large fish to the smallest plankton without having to proceed into the most highly contaminated areas.

These were subjected to radiochemical analysis in the laboratories on the *Haven*. The algae proved to have the highest activity; fish that fed on algae also had high activity (Hines, p. 44). Thus began a saga of measuring and following the behavior of radioactive contamination from fallout in an aquatic system that continued for many years. In the earlier years, the measurements were made largely by Geiger-Müller counters. There was little opportunity for identification of individual radioisotopes, and sensitivity was not high. Also, alpha emitters may have been missed. As the work progressed, the sensitivity improved, and there were opportunities to identify individual radioisotopes. We have reported the results in terms of the capabilities of the instruments in use at any given time. The reader should take this into account as the work unfolds.

For the short term, the activities found in all organisms around the lagoon led Welander (letter report quoted by Hines) to recommend that no fish, mollusk, or other marine animals taken within one hundred miles of Bikini Lagoon be used as food!

Some evidence developed that organisms were beginning to die on the north reef between Bikini and the adjoining Aomen Island. However, the operation was winding down, the support vessels and personnel were departing. All that could be done was to pack up the specimens for later examination and write a long list of things requiring additional study.

Operation Crossroads was intended as partly a demonstration to the assembled observers of the awesome power of the atomic bomb. Test Able disappointed many. Test Baker left no doubts. Test Baker also brought the potential problems of short- and long-term contamination from fallout vividly front and center. Fortunately, through careful planning, no human being was seriously contaminated or hurt by the radioactivity in these operations. Kudos go to all concerned, particularly the personnel from the medical department of the MED and the medical and support staffs from the U.S. Navy with help from the Public Health Service (PHS) and the Army. (a,b)

(a) *Note added in proof:* It now appears that contamination of men assigned to scrubbing down the decks of ships for Test Baker may have been greater than hitherto reported. Also, the dosimetry, especially a possible greater amount of contamination from alpha particles, and large errors in reading film badges have been brought up for further question (Marshall 1985). Some of this re-examination was stimulated by the opening of the files of Stafford Warren. It will probably continue. Nevertheless, these retrospective doubts do not negate the fact that the enormous dimensions of the operation, much beyond expectations, could have produced a serious debacle without the efforts of the biomedical community, naive as they now seem.

(b) *Second note added in proof:* A very readable retrospective review of Operation Crossroads appeared in a review by T. M. Daly (1986), as well as in the book by Hacker (1987).

III. The Pacific Proving Grounds

A. Overview

On the completion of Operation Crossroads, it was expected that the Bikini Atoll and all of the central Pacific could return to placid somnolence. There were some doubts about how soon the Bikini residents could return to their island, but it would have to be as soon as possible, for a commitment had been made. All of that was before it became clear that the Russians had detonated an atomic bomb (announced on September 23, 1949, by President Truman); before the realization that it would be relatively easy to tap the enormous power of fusion; before the Korean War; and before the Cold War. These events made it clear that testing of atomic weapons was far from over and that a remote site would be needed for testing of larger weapons, including hydrogen bombs, should such be developed. After consideration of many possible sites, including Alaska and the Indian Ocean, the decision was made to establish a proving ground back in the central Pacific in the general area already used in part but greatly expanded. (For details see Hines 1962, chapter 4.)

The development was, of course, gradual. There was first a resurvey of Bikini Atoll under the sponsorship of the new Atomic Energy Commission (AEC). This was planned before the decision to establish a Pacific proving ground. The enterprises were shifted from Bikini to Enewetak, partly because of the lingering radioactivity found on Bikini and partly for operational advantages. A map of Enewetak Atoll is given in figure 12.3.

The first tests were of fission devices and were centered mostly on improvements of design and efficiency. There were three shots in the Enewetak area in operation Sandstone, carried out in the spring of 1948. Yields ranged from 18 to 59 kt. Biomedical studies were not emphasized in this series, although there was some ecological work, and considerable aquatic biology was performed.

An interim of three years followed before any other major tests took place in the Pacific. This gave a very useful opportunity for the biologists to follow through on sampling of flora, fauna, and water for both radioactivity and possible development of biological effects. Then in 1951 came the "Greenhouse" series, in 1952 the "Ivy" series, and in 1954 the "Castle" series. By this time, we were well into the testing of thermonuclear devices, and the true dimensions of potential problems from fallout became very evident, especially with the 15-megaton "Bravo" shot.

Two years later, "Operation Redwing" took place at both Enewetak and Bikini with a few announced yields in the megaton range but none as large as the Bravo shot. After another two years, "Operation Hardtack" took place in two phases with Phase I at the Pacific Proving Ground. This involved not only Bikini and Enewetak, but also Johnston Island.

All of these detonations were in the decade of the 1950s. Few of them had overt biomedical objectives, but some enormous problems were forced upon the biomedical community by these events. This section will review primarily the biomedical aspects of the Pacific tests.

B. The Resurvey of Bikini

The biologists, most of them from the University of Washington Applied Fisheries Laboratory, were keenly aware at the end of Operation Crossroads of the need for follow-up at Bikini. The opportunity came sooner and more easily than

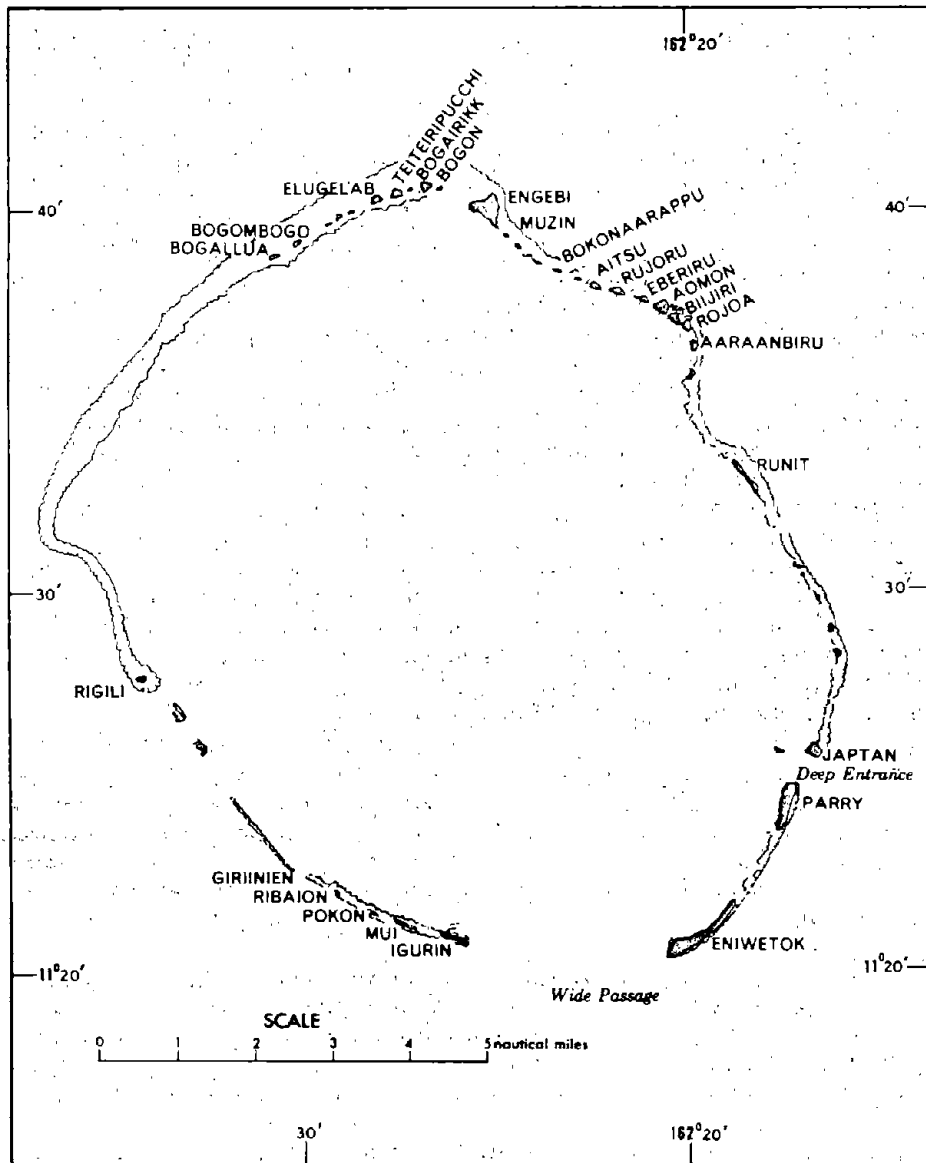

FIGURE 12.3. Eniwetok Atoll. (Modified slightly from Hines 1962. Reprinted with permission of University of Washington Press, Seattle, Washington, copyright 1962.)

expected, as Hines describes (chapter 3). The first resurvey became possible in the summer of 1947.

This operation included the fisheries group already described plus representatives from the U.S. Fish and Wildlife Service, other universities in addition to the University of Washington, the Hopkins Marine Station, the Scripps Institution of Oceanography, Oak Ridge, and others. A moderately large ship, the

Chilton, based at the San Diego Naval Station, carried the assembled group plus two radiochemistry survey facilities, a counter room, a fisheries laboratory, and an experimental biology laboratory. Some of the equipment was moved ashore on arrival at Bikini. There was one laboratory ashore devoted to morphological and physiological studies of plants and one for marine invertebrates. There were also accommodations for groups doing low-level radiation studies, geology, and aerology (Hines 1962).

The first observation came immediately on re-entry into the lagoon. The water that had been light green and crystal clear before the Baker shot was turbid and like mud in color. This phenomenon seemed to reside in suspended small particles from the grossly disturbed bottom. These particles kept picking up radioactivity from the sunken vessels and bottom sediments and in turn passing it on to the plankton residing therein and to larger organisms feeding on the plankton.^(a)

The chief interest was, of course, the extent and nature of the residual activity. There was ample evidence of very widespread residual radioactivity. Fission products were found in clams, snails, oysters, corals, sponges, octopods, crabs, sea urchins, sea cucumbers, spiny lobsters, shrimps, and in the fish caught in various areas. Concentrations in the fish were greatest in spleen, liver, and feces, followed by kidney and gonads. Highest contamination was still in the area of the detonation, but the profiles had extended much more widely than at the end of Operation Crossroads. Later there was increased emphasis on the presence of residual alpha-particle contamination from the devices.

None of the levels was considered high enough to produce acute radiation damage in any of the organisms. Examination of over one thousand species (tens of thousands of specimens), many of them having reproduced through one or more generations, failed to reveal evidence of aberrant forms, nor was there evidence of interference with reproduction. However, the marine ecosystem is not an easy one in which to spot any but large changes, and conclusions were very guarded.

There was reassurance in the finding that strontium and cesium, the most feared fission products, appeared to be absent. Plutonium was found, but in small quantity.

Nevertheless, the levels of radioactivity found were sufficient to raise doubts about the speedy return of the Bikini residents. The possibility of long-term effects and concentration of radionuclides in foodstuffs could not be denied. Furthermore, the biological data had raised as many questions as they had answered about the transport of radionuclides in such a diverse and complex ecosystem.

On their return home from the six-week summer sojourn, the laboratories worked hard on examination and measurement of the materials collected and on analysis of the data. One firm conclusion was that a further resurvey should

(a) Dr. Allyn Seymour (personal communication, June 1985), who was a member of the Bikini resurvey group, remembered these phenomena, but with slightly different timing. He recalled that the water was turbid and green at the end of 1946, but it was not very turbid in 1947. He also inclined toward the view that the phenomena may have been more due to overgrowth of plankton from nitrogenous waste deposits by personnel of Operation Crossroads than to direct results of Test Baker. Hines (1962) also mentions this possibility. In any event, things had changed.

be undertaken in the summer of 1948. They pointed out that "only through continuous long-term effort can we hope to understand the basic principles involved" (Navy Department 1947).

This further resurvey was accomplished, but on a much smaller scale because of activities at other atolls of the Pacific Proving Grounds. Many of the key personnel were invited to observe the new tests at Enewetak, and they had opportunity to collect marine specimens from some of the islands, e.g., Runit.

We will save further details of the aquatic biology and ecology findings for a special section.

C. Sandstone, Greenhouse, and Ivy

We will not attempt to recount step by step the biological efforts and findings associated with these three series of shots that went from the kiloton into the megaton range. Such a step-by-step analysis has been masterfully done by Hines. The radiological safety aspects will be made available in much detail by Hacker. We will instead enumerate a few highlights:

1. More detail could be discerned as instrumentation potential proceeded from permitting only gross beta radioactivity and crude measurements of alpha contamination to the separation of radionuclides and much greater sensitivity.
2. In 1949, a group was carried on a small ship (LSJ[L]1091) from Kwajalein to Bikini and then to Enewetak for sampling of everything possible.
3. Much more detail concerning radioactivity and possible effects in plants became available.
4. Studies were begun on animal life of the atolls, e.g., rats, coconut crabs.
5. Local coconuts and other crops contained residual activity greater than twice that of crops from outside the area.
6. The final shots of Sandstone were marred by the occurrence of beta burns in personnel removing air sampling filters from the cloud-sampling drones landing at Enewetak. The activity levels demanded abnormal haste. The members of the Radiochemistry Group had no relief workers to call upon and evidently cut corners by using gloved hands alone instead of gloved hands plus tongs, etc. (Hacker undated). These individuals were relieved of duty in the field and went back to Los Alamos along with the samples. They may represent the only cases of beta burns from fallout since the Alamo-gordo cattle.
7. Some aberrations in plant growth were found on Enewetak fifteen months after Sandstone. Some of the plants showed structural abnormalities, while others exhibited a physiological change called "die-back." The plant would begin to grow vigorously, but the young stems would turn yellow and the entire plant gradually wither back to its roots. Yet, the plants in the early stages produced viable seeds that went ahead and began growth only to wither back in turn. Unfortunately, these aberrations could not be ascribed definitely to radiation. They resembled phenomena such as calcium deficiency, a process that could not be ruled out in the close-in areas where the aberrations were most pronounced.
8. A few tumors appeared on plants near the Enewetak shots. It appeared that, if they were radiation induced, they were caused by direct radiation from the surrounding soil, not uptake of radionuclides through roots or leaves.

9. The Greenhouse tests in 1951 involved little return to the aquatic biology programs. Instead, animals (mice, dogs, and pigs) were exposed to the radiation and other effects of the blast, primarily to aid the development of treatment methods for atomic bomb casualties. Since this involves primarily external radiation problems, it will not be expanded upon here except to quote the opinion of Lieutenant General E. R. Quesada, U.S. Air Force, Commander of Joint Task Force Three as follows:

We have again operated in and around radioactivity. Our operations have indicated to us clearly that the mysterious ghost of lingering radiation should be dispelled. The immediate radiation, blast, and heat kill and destroy. Fear of lingering residual radioactivity must not confuse or delay prompt disaster operations in the event we are attacked.
(Quesada 1951)

In terms of objective (treatment of early casualties), this is a logical statement. However, in view of the possible enormous escalation of effects from radioactive fallout later revealed by Operation Castle, it needs some caveats.

10. In Operation Ivy, a small team of biologists collected samples from seven major stations rimming the Eniwetok Atoll, some of them used in the surveys of 1948 and 1949. There were pretest samples of algae, fish, and invertebrates and rats collected in traps before the test shot "Mike." Afterward, collection teams gradually re-entered, but for the first time since Baker were constrained by residual radiation levels that threatened to exceed "the cumulative exposure limits prescribed by RadSafe" (Hines 1962, p. 141). The data immediately showed that the levels of activity in many of the samples were so high that large amounts of radionuclides could be expected in the biome. For example, the plankton tows that in earlier shots had contained relatively low levels of radioactivity were two to three hundred times higher in the post-Mike shot samples (Hines 1962, p. 147).
11. The highest concentrations of radionuclides appeared in omnivores, probably because they added surface contamination from plant foliage they ate to that ingested via meat, etc.
12. By 1953, six years after creation of the Pacific Proving Ground, a more or less permanent laboratory for biomedical work was established on Parry Island. This was during the period when John Bugher was director of the AEC Division of Biology and Medicine. In addition to the people from the Applied Fisheries Laboratory of the University of Washington, the laboratory also accommodated scientists from the AEC New York Operations Office, and others. It was called the "Eniwetok Marine Biological Laboratory."
13. The Mike shot added a new dimension to the worldwide fallout problem, viz., injection of contamination into the stratosphere.
14. Some of the differences in dimensions of the fallout problems to the marine environment as compared to the terrestrial were reinforced along the lines described in chapter 11.
15. An inescapable conclusion was that, although the thermonuclear device theoretically produced less inherent radioactivity per unit of yield, the much larger yield could entrain enormous amounts of debris, and the high neutron flux could produce very large quantities of activation products. Thus, except for a very high altitude burst, the problems of fallout did not go away by shifting from fission to fusion.

D. Operation Castle, Shot "Bravo"—The Roof Falls In

1. The Event

On March 1, 1954, an experimental thermonuclear device was exploded on Bikini Atoll in the Marshall Islands with results far different from those expected. First, the yield was well above expectations, and the part of the atoll on which the device was detonated essentially disappeared as a huge cloud of coral mixed with fission products, activation products, and other debris. Second, the carefully predicted winds blew from the right way at the surface but from the wrong way aloft. Because of the high altitude to which the debris was carried (over one hundred thousand feet) and lack of knowledge of the wind directions up there and a shift of wind nearer the surface just after the test, the fallout went south over inhabited atolls and on the ships of Joint Task Force Seven. Also, the cloud dropped fallout over thousands of square miles of open ocean, far beyond the range of thermal and blast effects. As we all know, some of it fell on the 99.9-ton Japanese fishing boat named *Fukuryu Maru No. 5* ("Lucky Dragon" in English).

The story has been told in detail in many places, ranging from official reports of both the United States and Japan, through symposia (e.g., Cohn, Robertson, and Conard 1960), a graphic description by Hines (1962, chapter 7), to the *Saturday Evening Post* (Sherrod 1954).

Eighty-two Marshallese were evacuated from Rongelap and Ailinginae Atolls and 154 from Utrik Atoll to Kwajalein and later to Majuro Atoll. The 82 from the closest island showed significant biological effects and required considerable attention, as we will see. Those from Utrik were returned to their homes after some months. The total of Marshallese persons receiving measurable levels of gamma exposure from fallout came to 239 (Cohn, Robertson, and Conard 1960). The exposures included both external radiation doses and beta doses from suspended and deposited fallout, plus inhalation and ingestion exposures (especially on Rongelap and Utrik).

During the early hours, preliminary care and evaluations of the exposed populations were initiated by the station medical officer, Commander W. S. Hall. As soon as possible, medical and scientific teams were brought out from various U.S. installations, especially the NRDL in San Francisco (see chapter 13); the Armed Forces Special Weapons Project; the AEC's Division of Biology and Medicine; and the Naval Medical Research Institute in Bethesda.^(a)

In addition to the medical care and follow-up, much was done to ascertain the condition of and radionuclide contents of plant and animal life exposed to the fallout. This was done partly for its intrinsic interest and partly as an aid in determining the probable exposures of the humans.

Despite the fact that the events of March 1, 1954, set the stage for a marked "intensification on an international scale of medical and biological investigations related to the problem of nuclear fallout" (Hines 1962, p. 178), early

(a) A sample of the frenetic conditions behind the scenes can be gleaned from a personal interview with Stanton Cohn (Cohn 1982). In 1954, he was on the staff of NRDL and had been doing experimental work with radionuclides. He received word late one night to be prepared to depart as soon as possible on a secret mission and to bring along equipment and drugs for potential use in decorporation of radioactive materials from humans (see chapter 19). As we will see, this led to Dr. Cohn's twenty-five-year association with the problems of the Marshallese.

announcements and information from Washington were terse and uninformative. It was March 11 before an announcement was made about transporting of residents out of the area, and it stated, "There were no burns" (AEC 1954). It was not until the *Fukuryu Maru No. 5* reached its home port of Yarusu, Japan, that the lid had to be lifted, but even then it was done somewhat reluctantly in matters of detail.^(a)

Reports began to appear gradually during the succeeding weeks, and scores of meetings soon involved most of the relevant scientific community. A fairly complete listing of individuals and institutions concerned, at early as well as later phases, is given in the first relatively complete and unclassified document on the subject, issued by the AEC in 1957 (Dunning 1957a). Most of those participating are already familiar to us from earlier chapters, but it is interesting to note that AEC Headquarters staff took active roles, along with those from NRDL, the Applied Fisheries Laboratory, UCLA, and others.

Before we consider further details of the biomedical work, it is of interest to ponder further upon the very large quantity and extent of the fallout from Shot "Bravo." True, the shot was at least 15 megatons in yield, and it was close to the surface on a tower. Millions of tons of the substratum were dislodged and became airborne. But these suspensions are characteristically of fairly large particle size and should return to earth more or less within the radius planned upon by the test organization. Was the pulverization unusually complete or was there another factor?

Ralph Lapp considers these questions in his book *Atoms and People* (Lapp 1956) and concludes that no calculation using ordinary assumptions could account for the quantity and extent of the fallout. He decided that the Bravo device had a skin of natural uranium, which could be made to fission by the very energetic neutrons of the fusion process. Thus, the hydrogen bomb could have an added component of ordinary fission products, and these could be carried considerable distances, especially since some of the precursor substances were gases. Lapp was convinced that these contributed considerably to the exposures at a distance, such as the Japanese fishermen. He had no access to the secret data regarding the bomb, but he did get copies of a scholarly publication by Japanese scientists analyzing the fallout dust. They had found ^{237}U on the deck of the *Lucky Dragon*. Uranium-237 is a normal product of bombardment of ^{238}U by very fast neutrons. The ^{237}U was not in sufficient quantity to be radiobiologically important, but it confirmed Lapp's calculations.

This instance is mentioned primarily to emphasize that measures can be taken to increase fallout activities greatly and produce a very "dirty" hydrogen bomb. Such measures could include the fissioning of a natural uranium shell as above, or of a cobalt shell that can produce a very highly radioactive fallout in great quantity.^(b)

(a) It is not appropriate in this research compendium to enter further into discussion of the pros and cons of dissemination of information, or the reasons for the guarded attitudes. It does seem clear that the Marshallese and Americans exposed received care as rapidly as possible, despite lack of public information. Whether or not more could have been done for the Japanese, both the fishermen and the general populace who worried about contaminated food, is for others to say. The problem seems to have been in part one of attitude, or perceived attitude.

(b) As we will see in connection with Project Plowshare, measures can also be taken to reduce fallout and make a "cleaner" bomb.

Thus, the March 1, 1954, shot showed not only what ordinary fallout could be like from a large detonation at surface level but also what special features could be incorporated and should be considered possible in any projections of fallout effects from other devices. Indeed, the H-bomb might be regarded as a gigantic A-bomb rather than "clean" (Lapp 1956).

Figure 12.4A shows the apparent contours of the lower altitude fallout doses integrated for a two-day period. In figure 12.4B, the doses at specific atolls are shown. (a)

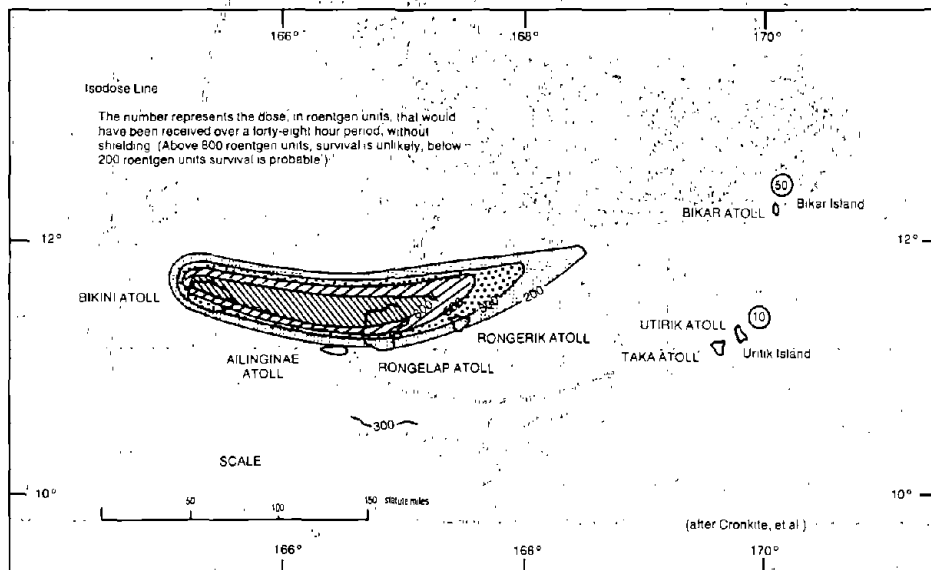

FIGURE 12.4A. General pattern of fallout from March 1, 1954, test at Bikini. (Modified slightly from Micronesia 1973.)

2. The Marshallese

The group of natives on the Marshall Islands accidentally exposed to the fallout from Shot "Bravo" required immediate medical examination and care. Also, they, with the twenty-six American military personnel who were on the island, represented the only population of human beings exposed to weapons-type fallout and, as such, they provided possible comparisons with the populations of the Japanese cities exposed to high doses of external radiation. Thus, the prospect of long-term care and study seemed very real. Although there were occasions when the patients wondered if all the fuss and repeated examinations was more for research than for them, (a) on the whole, the operation provided a unique mixture of needed medical care and the collection of important information.

(a) Indeed, examinations were suspended in summer 1960 to give them a breather and a chance to adjust to their return to their native island.

FIGURE 12.4B. More on radiation doses on individual atolls at the same time, approximately as the dose rate contours shown in figure 12.4A. (Modified slightly from Micronesia 1973.)

Early care was provided by the military and special-teams from laboratories such as the Naval Medical Research Institute, the NRDL, the Walter Reed Army Medical Research Center, and others. The first wave was directed by Dr. E. P. Cronkite. There was a resurvey at six months done under Dr. V. P. Bond, and another at twelve months done under Dr. Cronkite. Beginning in 1956, the center of operations shifted gradually to the Brookhaven National Laboratory (BNL) on Long Island, N.Y. This came about partly because some of the key physicians (e.g., Bond and Cronkite) moved from the NRDL and the Naval Medical Research Institute to Brookhaven, and partly because it became obvious that it would be a long-term operation. There thus began over a quarter century of continued work by the Medical Department at BNL, with numerous collaborators from other organizations (e.g., Case Western Reserve University; M. D. Anderson Hospital; University of Pittsburgh; National Institute of Health; Trust Territory of the Pacific Islands; Hiroshima University; National Institute of Radiological Sciences, Japan; U.S. Public Health Service; University College Hospital, London; U.S. Veterans Administration; etc.). The results appeared in a series of BNL reports and related publications that are listed, without the collaborators since there were too many, in the bibliography (Cronkite et al.

1955a,b; Conard et al. 1956, 1957, 1958, 1960, 1962, 1963, 1963-1964, 1967, 1970, 1975, 1980; and Conard 1977).^(a) Of these, the twenty-year review (Conard et al. 1975) is especially complete with background and history and is especially well illustrated.

The work is continuing, but with retirements of Conard and some of the other principals, the study has shifted largely to reconstruction of the dosimetry.^(b) This new work is being done largely in the former Health Physics Division, now Safety and Environmental Protection Division, at BNL, with reports already completed by Greenhouse and Miltenberger 1977; Greenhouse, Miltenberger, and Cua 1977; Greenhouse, Miltenberger, and Lessard 1979, 1980; Lessard, Greenhouse, and Miltenberger 1980; and Naidu et al. 1980.

While the work has been described in open literature publications and in the Congressional hearings cited earlier in this chapter, the BNL reports provide the most complete story. Generalized reviews were presented in AEC (1956), Dunning (1957a), Conard (1956, 1961) as well as in some of the journal publications cited.

It should be emphasized that the professional teams had a wide geographical and disciplinary base. There were medical observers from Japan and from the Congress of Micronesia, AEC observers, collaborators from the Atomic Bomb Casualty Commission (ABCC) in Hiroshima, and a cadre of medical and technical specialists from institutes throughout the United States and elsewhere.

The Congress of Micronesia developed a special joint committee and produced a report of its own under the Fifth Congress of Micronesia in February 1973 under the chairmanship of Senator Olympio T. Borja (Micronesia 1973). While the basic findings in this report coincide with those in the BNL and AEC reports, there are also some points of difference and an airing of some problems they felt were important and were not reflected fully in the American documents.

The basic sequence of findings and research progression is given in the following paragraphs:

1. In the first two days, some of the exposed people from Rongelap experienced anorexia, nausea, and vomiting. This was partly due to the gamma exposure and partly due to ingested material, estimated at about 3 mCi.^(c)

2. In about a week, beta burns began to show and were clearly evident by two weeks on the exposed flesh of the natives. There were marked variations depending upon location, whether or not they had bathed, etc. A typical example can be found in figure 12.5, which shows beta radiation lesions of the feet at four weeks after exposure and the sequence of healing.^(d) Interestingly, although some of the lesions, especially ones in folds of skin, became ulcerated, they remained relatively superficial. No skin cancer has yet been seen from any of these lesions.

(a) I am grateful to Dr. Conard for keeping me on his mailing list for many years and to Dr. Lessard for providing a complete set of these classic documents.

(b) The medical surveys are being continued under the direction of Dr. William Adams at BNL with collaborators.

(c) Fortunately, the material was relatively insoluble and passed through the gastrointestinal tract quickly. The gastrointestinal-tract symptoms lasted about two days and had largely disappeared by the time the people reached Kwajalein.

(d) Excellent color photographs can be seen in the AEC documents cited.

PLATE 5.—Hyperpigmented raised plaques and bullae on dorsum of feet and toes at 28 days. One lesion on left foot shows deeper involvement. Feet were painful at this time.

PLATE 6.—Lesions 10 days later: Bullae have broken, desquamation is essentially complete, and lesions have healed. Feet no longer painful.

PLATE 7.—Lesions 6 days later showing repigmentation except for small scar on dorsum of left foot at site of deepest lesion.

PLATE 8.—Same case as in Plate 5, six months later. Foot lesions have healed with repigmentation; except depigmented spots persist in small areas where deeper lesions were.

FIGURE 12.5. Beta radiation lesions of the feet four weeks after exposure and sequence of healing. (Photos from Conard et al. 1956.)

3. There were a few mild cases of epilation in the highest dose groups.
4. Blood counts were begun quite early. They showed significant lowering of leukocyte and platelet counts. This was most marked in the Rongelap people (estimated gamma dose, 175 rad) but was detectable in the Utrik people (estimated dose, 14 rad). The lymphocytes dropped to about half the normal level in adults and a quarter of the normal level in children under five years of age. Neutrophils fluctuated early but settled at about one-half the control level after five to six weeks. Of special interest is the slow recovery of the blood cell levels.

Only the neutrophils were back to normal at twelve months. It was not until the eleven- and twelve-year surveys that the hematological picture finally returned to levels comparable to those of the unexposed population of the area.

5. In later years, bone marrow samples were added occasionally for determination of possible chromosome aberrations. Some were found, but their significance could not be ascertained.

6. Considerable effort was expended to find the nature and extent of the contributions of radionuclide intake. This was accomplished early by the collection of urine samples. Later, the survey teams brought equipment from BNL for whole-body and organ counting. This included first a makeshift steel room and later arrangements of lead bricks as shown in figure 12.6.A and B.^(a) No measurements showed body or organ burdens of any radionuclide more than a small fraction of the maximum permissible burden. However, there was definite evidence even from the early urine samples that radionuclides had been deposited in the body. While it was clear that these deposits did not contribute much to the early doses, their persistence in the body and in the environment could obviously add up to potentially significant doses over the years.

FIGURE 12.6A. Steel room used for whole-body gamma spectroscopy on the Marshall Islands. It resided on Kwajalein between surveys. (Photo taken from Conard et al. 1975.)

(a) The steel room and other heavy equipment remained on the atoll. However, the electronics were too subject to the effects of humidity, heat, and sand to be left there; they had to be transported back and forth for each survey. Stanton Cohn tells of a harrowing incident on the return trip from the first whole-body survey. The plane (military) developed engine trouble over the Pacific, and much expensive counting equipment had to be jettisoned to lighten the load. Also in their zeal to keep airborne, the crew jettisoned all of the data, originals that were waiting to be reproduced on return to the mainland and of which there were no copies (Cohn, 1983).

FIGURE 12.6B. Arrangement of lead bricks used for whole-body counting. This replaced the steel room and was made possible by improved electronics. (Photo taken from Conard et al. 1975.)

The estimated early body burdens of several radionuclides in the Rongelap people are given in table 12.1. Note that the early activity for ^{131}I in the thyroid is the highest, with ^{89}Sr (not ^{90}Sr) in second place, and that cesium is not even mentioned. For comparison, figures for 1970–1974 for several isotopes in individuals from three islands are shown in table 12.2. Note that the activities in urine do not vary much from year to year and that ^{137}Cs in this period greatly exceeds the amount of ^{90}Sr . Such results indicate that the radioisotope contents are being continually replenished from the environment. Almost none could be left, except perhaps a little strontium in bone, from the original depositions. The gamma spectra from the whole-body counting showed a pronounced peak at the ^{137}Cs energy level in the Rongelap subjects, much less in members of the BNL medical team. The quantities were in the range of a few nanocuries per kilogram body weight.

TABLE 12.1. Estimated Body Burden (μCi) of Rongelap People

	Activity at 1 day	Activity at day 82
^{89}Sr	1.6 - 2.2	0.19
^{140}Ba	0.34 - 2.7	0.021
Rare earth group	0 - 1.2	0.03
^{131}I (in thyroid gland)	6.4 - 11.2	0.0
^{103}Ru	0 - 0.013	—
^{45}Ca	0 - 0.019	0.0
Fissile material	0 - 0.016 (μg)	0.0

Source: Reset from Conard et al. 1975.

7. A few bone samples were obtained from autopsies of individuals dying from causes that were, with one exception, not related to radiation. The ^{90}Sr found in these bones gave calculated body burdens that agreed well with those calculated from urinalysis.

TABLE 12.2. Radiochemical Analyses of Urine (Data in Average pCi/liter)

8. There was no question but the burdens of several radioisotopes began to climb soon after the return of the population to Rongelap in 1957. The contents of strontium and zirconium (from eating fish primarily) peaked at about 1960-1963 on Rongelap, but the ¹³⁷Cs burdens held high much longer. Indeed, it is ¹³⁷Cs in the soil that is one of the current concerns about the Bikinians and that resulted in their being taken off their island again. (A few had been repatriated.)

9. One source of continuing replenishment of the body burden of ¹³⁷Cs and of ⁹⁰Sr is the coconut crab. This large creature, capable of puncturing a coconut and long a staple in the diet of the Marshallese, has been measured regularly and found to be consistently high in both ⁹⁰Sr and ¹³⁷Cs. Some typical data are shown in table 12.3.

Despite warnings not to eat the coconuts or any other produce from the local soil,^(a) the Marshallese could not resist (or possibly they did not understand fully the reasons for the prohibitions). They were undernourished. Coconut crabs were a great delicacy, especially when the alternative was C rations. While the local fish were gradually decreasing in radioactivity, and thus the intake of isotopes like ⁶⁵Zn from them was constantly reduced, the land-bound animals

(a) Extensive gardening was attempted to help reduce dependence on imported foods and to make the islanders' life style more nearly normal. This did not work. The crops picked up too much radioactivity from the soil.

and plants could and did act as a large reservoir for maintaining significant levels of radioactivity in the population, a largely unexpected result.

10. A large number of other health determinations were made and showed essentially no effect of the exposure over the first decade. These included general health, disease resistance, nutrition, growth and fertility, and incidence of cancer. Indeed, there was a fairly prolonged "silent period" after the initial effects had cleared.

11. By the time of the nine- and ten-year surveys, changes in the thyroid gland began to appear. Three exposed teen-age girls showed thyroid nodules. Three more cases appeared in the eleven-year survey, two in boys twelve to seventeen years of age, and one in an adult woman of forty-one years. By the twelfth year, there were eighteen cases of thyroid dysfunction, sixteen with nodules, and two with hypothyroidism. At later times, effects could be seen as growth retardation, particularly in some of the boys. This was reversed by treatment with thyroid hormone started in September 1965. Reviews have been published by Conard et al. (1969), Larsen et al. (1978), and others. The picture in March 1969 is shown in table 12.4. Typical calculations of dose along with data on incidence by December 1974 are shown in table 12.5. It appears that the early calculations failed to consider the possibility of a much larger dose to the thyroids of children because of the small size of the thyroid in the child.

As might be expected, these findings led to much emphasis on thyroid and thyroid-related effects in all of the subsequent work. Some of the patients were flown to the United States for more careful measurement of their body and organ burdens, first at Argonne National Laboratory (ANL) where C. E. Miller had just set up whole-body counting (chapter 18), later at BNL. Some were brought over for thyroid surgery in New York, Boston, and elsewhere.^(a)

(a) A question has been raised regarding the seriousness of some of the cases since a handsome sum was paid by the U.S. government to individuals requiring thyroid surgery. Medical supervision was competent, honest, and tight and allowed little chance for maligning.

Source: Modified slightly and reset from Conard et al. 1970.

The growth retardation was greatest in those receiving the dose at the early critical stages of growth. Thus, there were cases of the older of two siblings (both boys) being considerably shorter than the younger. After eight years of thyroid hormone therapy, the two boys were of nearly equal height. These are pictured by Conard et al. (1975) and in AEC publications.

Much additional work that was done to assess thyroid function cannot be reviewed here. Suffice it to say that ample details appear in the BNL reports, and they include biochemistry and histology in extenso.

Fortunately, it appears that no one proceeded to fatal thyroid neoplasia, but thyroid cancer did occur; the results raised questions about our knowledge of the sensitivity of the human thyroid. The calculated radiation doses, particularly in adults, were lower than those expected based on general clinical findings and animal experiments (chapter 8) to be associated with such a high incidence of effects (nodules). Are the Marshallese especially sensitive, or was there some mistake in the dosage estimation? Were the total doses actually higher than those calculated from the measurements of fallout and urinary excretion? A significant portion of the BNL work is now directed toward reviewing and reanalyzing all information to double-check the doses and to obtain whatever new data are possible.

The re-evaluation involves the pooled urine analysis data in the light of current retention models, reestimation of airborne concentration of radioiodines on the basis of neutron irradiation of ¹²⁹I deposited in the soil, manipulation of meteorological models, and reanalyses of Bravo debris. There was a BNL report reconstructing the possible chronic doses at Rongelap and Utrik (Lessard, Greenhouse, and Miltenberger 1980) and one on internal exposure to the Marshall Islands residents from ¹³⁷Cs, ⁶⁵Zn, ⁹⁰Sr, ⁵⁵Fe, and ²³⁹Pu (Lessard,

^a Dose from ¹³¹I, ¹³²I, ¹³³I, and ¹³⁵I plus gamma; mean dose extrapolated from calculations for adults and 3-year-olds.

^b Based on number of people exposed, excluding those *in utero* (number of cases/total number in group).

^c The thyroid is considered to be fully developed by about age 18.

^d One additional case of adenoma; found at autopsy, not included here.

^e Weighted mean dose.

^f Pathologists differed as to whether this lesion was malignant; it was scored as benign.

^g The more energetic, shorter-lived isotopes of iodine contributed less to the total thyroid dose in the Utrik people because the fallout occurred later there. It might be surmised also that the biological effectiveness of the thyroid dose per rad would be less in the Utrik group.

*External dose.

Source: Modified slightly from Conard et al. 1975.

Miltenberger, and Cohn 1980). Dose contributions from these during the rehabilitation period exceeded the external dose equivalent received during that time but did not contribute significantly to the thyroid dose. There is also a large report in draft stage on bioassay and dose assessment for Bikini Island residents (Miltenberger et al. 1983) that we will await eagerly. (See preliminary publication by Greenhouse, Miltenberger, and Lessard 1980.)

Although the above comprehensive analysis of the exposures from all important radionuclides is still being compiled, the Brookhaven group issued a complete reconstruction of the thyroid dose. Lessard et al. (1985) concluded that the mean population thyroid doses received on March 1, 1954, were

2,100 rad (21 Gy) at Rongelap, 670 rad (6.7 Gy) at Sifo, and 280 rad (2.8 Gy) at Utrik. These increased dosage estimates brought the corresponding risk figures much closer to those estimated from the populations exposed at Hiroshima and Nagasaki and other estimates of thyroid-risk in humans. They put to rest, in a general way, the nagging inconsistencies that had persisted concerning the thyroid effects seen and the earlier estimated doses. They also concluded that ingestion was the primary route of entry.

A major contribution to the increased estimate of total dose appeared to be inclusion of all of the radioiodines and tellurium, rather than ^{131}I alone. Thus, the total from these was 7.7 times the absorbed dose from ^{131}I at Rongelap, 10 times at Sifo Island, and 4.7 times at Utrik Island. Bioassay results for ^{131}I seemed to be reasonably reliable if these factors were considered, but some other approaches, such as the use of ^{129}I , did not contribute as much as had been hoped. Thus, after thirty years, which included over a decade of work on the dosimetry, the medical observations and dosage reconstructions have been brought into reasonable agreement, a considerable feat in view of the complexities involved.

Open literature publications bearing on the dosimetric aspects and modeling have also appeared; see, for example, Lessard, Miltenberger, and Greenhouse (1980) on dietary radioactivity intake by the Bikini Island residents; Greenhouse, Miltenberger, and Lessard (1980) on the dosimetry in general; and Miltenberger, Greenhouse, and Lessard (1980) on whole-body counting results.

12. We mentioned that no excess malignancies, except for thyroid neoplasias, appeared in the earlier surveys, and even the thyroid cases appeared quite late in the total survey period. In 1972, an exposed Rongelap male died of leukemia at age nineteen at the National Institutes of Health (NIH) Clinical Center in Bethesda, Maryland, where he had been brought for urgent treatment. He had received 175 rad of gamma radiation at age one and had showed the early transient gastrointestinal symptoms. At age thirteen, he had developed thyroid nodules and was one of those taken to the United States for study and surgery of benign nodules. Review of the hematological and other data supported the possibility that this leukemia was associated with radiation exposure.

Despite the tentative nature of the evidence for causation, this case caused a considerable stir. It was decided immediately to do complete hematological examinations of the exposed Marshallese every six instead of every twelve months. The Micronesian Congress paid considerable attention to the development, possibly because leukemia is relatively rare in that population.

There was a slightly increased incidence of other cancers in the exposed Rongelap people at later times, but it could not be correlated with radiation exposure because of the smallness of the group, uncertainties in diagnosis, and the fact that the malignancies were not like those connected with radiation exposure of the Japanese as determined by the ABCC.

The care and study of the Marshallese is still continuing. One of the thorniest problems has been final repatriation of the entire population and the question of whether or not many islands should be scraped to reduce contamination, as was done for some. The body burdens of radionuclides of individuals that moved back to Bikini showed alarming tendencies to rise with time. Some of those on other atolls rose also, but to a lesser degree.

These phenomena may have meant primarily that the fairly rigid dietary prohibitions were not being observed. Or perhaps there were some miscalculations in the potential biological availability of the contaminants in the soils. The

debate is still continuing, and the research efforts being applied are largely extensions of what we have already reviewed:

The continuing rise of ^{137}Cs in the residents led to their re-removal from the area in 1978. This was not only a bitter reverse for these happy people, but a somber indication of how far into the future the consequences of fallout contamination may extend, this time largely through gardening in contaminated soil.

Unfortunately, the age of contention and litigation has reached even to the Marshall Islands. There are now more biopolitical problems than scientific. Each exposed native has received a generous financial settlement from the U.S. government, but this is considered no substitute for being able to return to one's homeland. The process has occupied more and more attention in the Department of Energy Headquarters (Deal 1979, 1980), and several large "in-house" reports deal extensively with these problems (e.g., AEC 1974; Bair et al. 1977; Clusen 1980; Kohn and Dreyer 1982). There was in addition a Bikini Atoll Rehabilitation Committee that operated under the Department of Interior. Its first report was submitted to the U.S. Congress, House and Senate Committees on Interim Appropriations (BARC 1984, 1985). This report concludes that the hazards of resettlement of Bikini Atoll stem almost entirely from the presence of ^{137}Cs . Strontium-90 plays only a minor role, and plutonium is not mentioned. It also concludes that Bikini could be resettled now and meet federal radiation protection standards, but only if no foods were grown or ground water consumed for a period of eighty years. Eneu could be resettled and meet federal radiation protection standards if a portion of the needed food, depending on population size, were imported. This solution was not acceptable to the Bikini-Kili Council, who want the sites decontaminated. The Committee is now working on potential plans for attacking the problems directly (e.g., "removing the top 30 cm of Bikini's soil") and needed pilot studies. The committee was chaired by Henry I. Kohn, professor of radiation biology emeritus, Harvard Medical School. He was assisted by A. S. Kubo, BDM Corporation; F. L. Petersen, University of Hawaii; and E. L. Stone, professor emeritus, Cornell University. (a)

A considerable effort has been made to present full discourses to the Marshallese on the exact meaning of the radiation on the atolls and the reasons for the various decisions made. These books were prepared for the Department of Energy by William J. Bair, Battelle, Pacific Northwest Laboratories; John W. Healy, Los Alamos National Laboratory; and Bruce W. Wachholz, Office of Environment, Safety and Health, U.S. Department of Energy (Bair, Healy, and Wachholz 1979, 1980, 1982) in what must be characterized as purely a labor of love. They were joined in close collaboration by translators, Alice Buck, Honolulu, Hawaii; and Meleran-Jelke and Kiorong Sam, Republic of the Marshall Islands, Trust Territory of the Pacific Islands. Technical editor was Ray Baalman, Battelle, Pacific Northwest Laboratories. The dose estimates were supplied by W. L. Robinson and colleagues at Lawrence Livermore Laboratory.

These three books, covering different atolls, are printed in both Marshallese and English on facing pages and are profusely and beautifully illustrated. As a

(a) Note added in proof: The June 1986 issue of *National Geographic* magazine contains a review of the problems of the Bikini natives (Ellis 1986). Unfortunately, it is a very incomplete review in that it concentrates only on very recent work and omits much of the enormous effort summarized in this chapter. Dr. Conard is pictured but not identified. There can be no argument, however, with Ellis's basic conclusions.

nontechnical account of all that went on of pertinence to the situation of the Marshallese, these discourses could, with amplification and generalization, serve as important primers to the general public on the subject of environmental contamination by radioactivity from fallout.

Despite all of these efforts, a referendum is about to be held to determine whether or not to sue the U.S. government and to find ways for the Marshall Islands to become independent of the United States. Resentment runs deep, and it resides in part in misunderstanding despite everyone's best efforts (see, for example, Appendix I to the review by Conard et al. [1975].)

With or without suits, we must conclude that the Bravo shot and its sequelae changed many views about fallout. About seven thousand square miles of territory downwind from the point of detonation were contaminated to the point that survival might have had to depend upon prompt evacuation or upon taking appropriate substantial shelter. (AEC 1955) had the areas been populated rather than largely open ocean. Also, while it should have been clear from the results of the first megaton-size bursts two years before, these events laid to rest permanently the idea that such very large explosions would eject the debris out of the earth's gravitational field, an idea considered seriously by some. The rest is more appropriately held for our discussion of worldwide fallout.

3. The Lucky Dragon and Sequelae

a. The Events

The exposure of the Japanese fisherman on the *Fukuryu Maru* No. 5 (*Lucky Dragon*) did as much, if not more, to bring fallout problems front and center on the world scene as the exposures of the populations on the atolls of the Pacific. Even though the *Fukuryu Maru* was moderately close to the announced danger zone, it was not actually inside of it, i.e., the calculated danger zone prior to the test. Unfortunately, the ship constituted such a small speck on the vast areas of open water that the reconnaissance planes missed it on their sweeps prior to the test. Also unfortunately, for reasons embedded in the strong relationships between Japanese workers and their employers, the ship never broke radio silence to ask what was happening, even though they saw the flash of the detonation.^(a) Instead, the ship plodded back to Japan with the twenty-two fishermen receiving daily doses from the accumulated fallout on the decks and their bodies and taking no special precautions to protect themselves or their catch of fish. The uproar began soon after the arrival of twenty-two sick fishermen at their home port of Yazu on March 17, 1954. This was soon viewed as crass disregard of Japanese interests on the part of the U.S. government, and it revived many of the only partially submerged emotions from Hiroshima and Nagasaki. Besides the sick fishermen, much concern focused on contamination of seafood, especially tuna. Many Japanese fish markets closed altogether. Fishermen were thrown out of work. A nation dependent on the sea for a substantial part of its food supply developed what was referred to in the press as "a great worry."^(b)

(a) Details of the many sociopolitical aspects of the incident are available in much of the literature already cited. A very graphic description can be found in Hines (1962), also Sherrod (1954), and the Congressional hearings already cited.

(b) It will soon be apparent that the Japanese did much more than worry.

True, there was a delegation sent from Washington, and the ABCC in Hiroshima offered full assistance. But there was an atmosphere of mistrust in the population verging on violence. Merrill Eisenbud (then head of the AEC Health and Safety Laboratory in New York, which had primary responsibilities for monitoring fallout) was one of the first Americans to reach Japan after the incident. When he arrived, he was met by an angry mob and for a while feared for his life (Eisenbud 1979).^(a) However, cooler heads prevailed, and, while there was need for much diplomacy on both sides, the Japanese dedication to good science predominated, and work began immediately to characterize and quantitate the situation. The Japanese did some excellent scientific work both in identifying the radionuclides in the residual fallout on the *Fukuryu Maru* and in monitoring the tuna and other seafood as it entered Japanese ports. Ultimately, over a million pounds of fish from about a thousand boats were tested. Of these, about 4% to 5% were found to be over limits and were buried or thrown into the sea.

Pictures of the *Lucky Dragon*, of some Japanese monitoring tuna, and a sign at a Japanese fish market are shown in figure 12.7A, B, C, D.

FIGURE 12.7A. The *Fukuryu Maru* No. 5 during her period of quarantine. (Reprinted from Hines 1962 with permission of University of Washington Press, Seattle, Washington, copyright 1962.)

(a) He was soon joined by Lauren Donaldson from the University of Washington and W. R. Boss from AEC.

FIGURE 12.7B & C. (Above and Right) Radiation survey of tuna conducted by Tokyo Metropolitan health authorities at the Tokyo Central Fish Market, 1954 (Sanitary Examination Laboratory, Tokyo). (Reprinted from Hines 1962 with permission of University of Washington Press, Seattle, Washington, copyright 1962.)

FIGURE 12.7D. (Left) Sign at fish market in Japan, March 1954. (Courtesy of Eisenbud 1976.)

The permissible radioactivity level was set at one hundred counts per minute measured on a beta-detecting Geiger-Müller counter at 10 cm from the body of the fish. This was considered a temporary "urgent" standard (Hines 1962, p. 175). However, except for possible hot spots, it probably provided sufficient protection from any health effects except the psychological trauma of eating fish with even one count per minute of what the Japanese called "Bikini ash." Incidentally, the distribution was very spotty. As Eisenbud (1976) described, one could monitor one hundred fish and find nothing, only to find a hot spot on the one hundred and first.

The medical care and eventual outcome of the sick fishermen were more complex. The physicians from the ABCC tried to help out, but there were many jurisdictional and professional problems.^(a)

This author has found few estimates of the total dose the fishermen might have received in their seventeen-day ordeal. Eisenbud made one in an oral presentation that this author was privileged to hear and of which he has a recording (Eisenbud 1976). Eisenbud's guess was a deposition of as much as 30 Ci/m² on the boat and an accumulated dose of up to 1,000 rad of beta-gamma and beta radiations. Japanese estimates were on the order of 500 to 600 rad (Suzuki 1956 and undated). No wonder the fishermen were sick!

In a sense, the ultimate effect of the *Lucky Dragon* incident plus the contamination of the Marshall Islands area was a watershed in the history of attitudes regarding the importance of fallout and the consequences of nuclear warfare. Even though the distribution might still have been regarded as "local" in contradistinction to "worldwide" (section VI), the potential areas and doses entered an entirely new category of significance. (Seven thousand square miles at dangerous levels of radioactivity is a substantial area!)

As cooperation between Japanese and American scientists became easier, several meetings and conferences were held. These have been described as increasingly cordial and informative, especially when the Japanese became convinced that the U.S. scientists were keenly interested in sharing all possible knowledge with them, and as it became apparent that the data being shared from the two sources were in basic agreement. Perhaps the area of most consistent agreement was on the activities and composition of the fallout and the activities in seafood. Since the Japanese had no access to data on the bomb itself, they went ahead on their own and constructed a very accurate picture of what had gone on. Dr. Kenjiro Kimura, a noted Japanese radiochemist and dean of the Faculty of Science at the University of Tokyo, and colleagues^(b) elsewhere worked out not only the basic story but even the presence of ²³⁷Np and ²³⁷U. The latter of these confirmed the calculations of Ralph Lapp as mentioned earlier. Also, Japanese scientists worked out the contents of the contaminated fish in detail (e.g., Dr. Toshihara Kawabata of the National Institute of Health, and others; see Hines 1962, chapters 7 and 8). Figure 12.8A shows Dr. Kimura at a ceremony where some of the radiochemical findings were announced. Figure 12.8B shows one of the early meetings of American representatives with the Japanese.

Meanwhile, back in Washington, the Joint Committee on Atomic Energy of the Congress held urgent hearings and special meetings. There was much controversy and acrimonious debate over the biological significance of fallout. A picture of one such meeting is shown as figure 12.9.

(a) There seems to have been much difference of medical opinion about some of the findings in these patients, including the question as to whether the one death from hepatitis resulted from the radiation exposure or a transfusion problem. All of the patients had drastically lowered white cell counts and followed clinical courses somewhat similar to those of the Marshallese, except that their blood cell counts seem to have returned to normal sooner (Kumatori 1975).

(b) The extent of the Japanese research effort can be found in a document entitled *Annex to Research in the Effects and Influences of the Nuclear Bomb Explosions* (Japan Society for Promotion of Science 1956). There were six major committees: for physics and chemistry (chaired by Dr. Kimura); for biology (chaired by Y. Okada); for medicine (chaired by R. Kobayashi); and for fisheries (chaired by Y. Okada).

FIGURE 12.8A. (Right) Dr. Kenjiro Kimura, noted radiochemist, at conference discussing Japanese findings. They had analyzed the "Bikini ashes" and had described the nature of the reactions involved within three days after the return of the *Lucky Dragon*. (Courtesy of Eisenbud 1976.) Note: Other Japanese scientists participating in the work and the arrangements are detailed by Hines 1962, chapter 7, p. 189 et seq.

FIGURE 12.8B. Early meeting of American representatives with Japanese concerning the exposed fishermen. Foreground, at right, Dr. John Morton, Medical Director of the Atomic Bomb Casualty Commission (on leave from the Chair of Surgery at the University of Rochester) and third on the right Merrill Eisenbud, Director of AEC's Health and Safety Laboratory. (Courtesy of Eisenbud 1976.) Identification of the others has not been practical.

FIGURE 12.9. One of several meetings of American scientists called by the Joint Committee on Atomic Energy of the U.S. Congress to discuss the biomedical significance of fallout. They are, from left to right, J. L. Kulp, Columbia University; W. F. Neuman, University of Rochester; Lt. Col. Hartgering, Walter Reed; W. H. Langham, Los Alamos; and Merrill Eisenbud, AEC Health and Safety Laboratory. (Courtesy of Eisenbud 1976.)

This last picture is shown partly because it involved some people whose work we have met elsewhere in this book and partly because it was these meetings that led to Cabot Lodge's request to the United Nations General Assembly that resulted in the founding of the United Nations Scientific Committee on the Effects of Atomic Radiation, UNSCEAR (Eisenbud 1976).^(a) All individuals in the picture agreed that definite and immediate limitations on nuclear explosions were necessary.

b. The Sequelae

The *Lucky Dragon* incident brought, among other things, urgent demands for determination of the extent and movement of radioactivity in the Pacific Ocean and the role played by living organisms. The Japanese were fearful that the contamination would move inexorably to their shores, contaminating their best fishing grounds on the way and even deny them the use of their beaches. Several expeditions were commissioned over the next few years to sample the waters and the organisms (see Hines 1962, chapters 7 and 8). These included:

1. A Japanese expedition that got under way on May 15, 1954, which used the *Shunkotsu Maru* and sampled over nine hundred thousand square statute miles of the Pacific.
2. A cruise by the *Keiten Maru*, a ship from the Faculty of Fisheries of Kogashima University between October 28, 1954, and January 28, 1955. It cruised largely in the Coral Sea.

(a) UNSCEAR has continued and represents an important source of authoritative and balanced information from international sources.

3. Three representatives of the Nankai Regional Fisheries Laboratory who made radiological samplings on a regular fishing cruise to the Fiji Islands between November 30, 1954, and February 19, 1955.
4. Operation Troll, a U.S.-sponsored project involving the Office of Naval Research, the AEC, the Scripps Institution of Oceanography, and others, with advisors or participants from every marine science laboratory in the United States. This was a fairly leisurely enterprise compared to the urgency of the Japanese cruises. It utilized the Coast Guard cutter, *Roger B. Taney*, and started its first survey on February 25, 1955. It did not return until May 3 after covering over seventeen thousand statute miles.
5. A cruise starting in June 1956 during Operation Redwing that utilized the destroyer escort, *USS Walton (DE-367)*. This ship was converted extensively to assist sample-taking and continuous monitoring of the activity in the surrounding sea water. Its survey area finally covered seventy-eight thousand square miles.
6. A cruise by the *USS Marsh (DE-699)* that followed up any contamination added by the shots of Operation Redwing.^(a)
7. As part of the "Operation Hardtack-Phase I" series in the Pacific in 1958, three sea surveys were involved. The first used the *USS Rehoboth (AGS-50)*, a seaplane tender converted by the Navy for oceanographic work. Later, with all the equipment transferred over from the *Rehoboth*, the *USS Collett (DD-730)*, a destroyer, was brought into service for surveys in the Central Pacific. Finally, after conclusion of the Pacific tests, a westward survey was done by the *USS Silverstein (DE-534)* (Hines 1962, p. 275).

There were underwater shots in the Hardtack Series, e.g., test "Wahoo," which involved a detonation at a depth of five hundred feet in May 1958. A primary purpose of the survey of the *Rehoboth* was to map out the spread of contamination from the underwater shot at the surface and at various depths. It could also add greater sophistication to the radioisotope determinations since there was a gamma spectrometer aboard the *Rehoboth*. A second underwater shot, test "Umbrella," detonated on the floor of the Enewetak Lagoon on June 8, 1958, involved the *Collett* in August. In September, the more wide-ranging cruise of the *Silverstein* took place. All of these involved sampling of biota as well as water, but only the *Silverstein* survey could be regarded as having the same long-distance objectives as the sea surveys operated shortly after the *Lucky Dragon* incident.

8. In addition to these extensive cruises, there were frequent surveys of the "local" waters of the Marshall Islands, as well as many terrestrial surveys by shore parties visiting the islands. Much of the former was done by people from the University of Washington and the latter by people like Frank Lowman, temporarily assigned to the Eniwetok Marine Biological Laboratory.

We can report a few of the results of these enormous undertakings:

1. The westward movement of the contamination stopped well short of the shores of Japan, deflected apparently by strong currents parallel to the Japanese coast.

(a) Maps of each of these cruises are given by Hines 1962, chapter 8.

2. Activity was easily measurable as far west as Guam, 1,200 mi west of Enewetak, but was only slightly above background at Palau, 1,950 mi west of Enewetak. It was not detectable in the Gulf of Siam, 4,250 mi from Enewetak. These phenomena are shown graphically in figure 12.10. Even more extensive measurements, some of them part of Operation Troll, showed radioactivity as far away as the Philippines, but still nothing in Japanese waters.

FIGURE 12.10. Average gross beta activity of marine organisms from Guam, Palau, and the Gulf of Siam, 1958–1959. Average based on two to thirteen observations. The original contained data also for fish muscle, spiny lobster liver, and hermit crab skeleton. Note: *Tridacha* is a clam. (Modified from Seymour, 1963b. Reprinted with permission of Van Nostrand Reinhold, Inc., New York, copyright 1963.)

- Of all the organisms collected at sea, the plankton contained the highest concentrations relative to the surrounding water. The average ratios of plankton activity to seawater activity varied, but were very significant, e.g., seven thousand times the surface water in the *Taney* survey, two thousand times the surface water in the *Marsh* survey.
- Radioactivity in other life forms reflected that in plankton, modified by the place the given form occupied in the food chain and the extent to which it fed on plankton or on organisms that consumed plankton.
- The continuous monitoring of the sea water was made possible by an ingenious device invented by Harry Levine at the New York Operations Office

and watched over by John Harley. Except for gradually becoming contaminated and thus operating at higher and higher background levels, it worked very well.

6. There were significant differences in the distribution of fallout radionuclides between marine and terrestrial environments. Fission products played an unexpectedly small part in the marine environment samples around the Pacific Proving Grounds. Much of the activity in plankton and in many fish samples was from radioactive cobalt, zinc, iron, etc., activation rather than fission products. Strontium-90 was much less prevalent than in terrestrial environments.^(a) It was suggested that the strontium (as well as the cesium) was being carried to the ocean bottom by the coral dust in the fallout.
7. Many previously unknown currents were found in the Pacific through tracing the movement of radionuclides.
8. There was no question that the biota contributed to the persistence and transfer of fallout radionuclides in the sea. Instead of filtering gradually to the bottom and staying there, the radionuclides were taken up by plankton and then passed up the food chain again. Also, the plankton themselves helped to move the radioactivity by their diurnal migrations in response to the light cycle and their movement with currents. This phenomenon was of greater importance in shallow water areas with abundant life than in the open Pacific.
9. Migratory forms of sea life could, to a small degree, bring contamination to areas that would not have received it otherwise.
10. Despite the magnitude of the effort, we must remember that these measurements were still essentially spot-checks of a vast area. Even though the later, more leisurely cruises gathered more samples and covered more points, we cannot guarantee that some "hot spots," such as those described in and around the Nevada Test Site (see later section), were not missed. Fortunately, if any did occur, they had a high probability of being in areas uninhabited by people.

4. Marine and Terrestrial Biota at the Pacific Proving Grounds

Much of the research not yet cited was more pertinent to the effects of external radiation than to the movement and effects of radionuclides in fallout. Yet, there is substantive work that has been touched upon only lightly elsewhere in this chapter. This section presents a brief review of these studies using the chronological format we have tried to follow throughout this book. The work on biota and ecological aspects continued long after the testing of weapons ceased. The NRDL went out of existence (chapter 13), but new blood was added by the entry of the Lawrence Livermore Laboratory (LLL).

a. The 1950s

The immediate surveys of the contaminated islands included, in addition to the work on aquatic forms, the collection and evaluation of domestic and wild animals and collection of many plants. In the first major published work (AEC 1956), a section is devoted to internal contamination of animals. Chickens, chicks, swine, ducks, and one cat were collected from Rongelap and Utrik and

(a) Note that this same phenomenon was noted in the long-term Columbia River surveys (chapter 11).

shipped to the United States NRDL, along with some fish and a large clam. Also, a few animals that died in the field were necropsied, and tissues were collected.

Urinary excretion showed appreciable amounts of ^{89}Sr , some ^{140}Ba , and rare earths in a quantity between the strontium and barium. From excretory measurements and tissue content measurements, body burdens were estimated and their decrease with time shown to be consistent with laboratory findings. Also, autoradiographs of the long bones from chickens and pigs showed heavy deposition of activity (mostly the alkaline earths) in the calcified areas, again consistent with laboratory findings with the fission products. Ninety percent of the activity was in the skeleton.

Fertility and hatchability studies were carried out on chickens beginning at 3.5 mo after detonation. There were essentially no significant differences from unexposed chickens.^(a) Fertility of the hens remained normal too.

It turned out that the level of internally deposited radioisotopes in the pigs of Rongelap was an order of magnitude higher than in the Marshallese people because of the more prolonged residence of the animals in the contaminated area. The chickens matched the pigs on a per unit body weight basis (AEC 1956, p. 91).

Fish caught in the waters of the lagoon were considerably more contaminated than the land animals studied in these early surveys. Also, much more of the total beta activity was in the viscera of the fish than in the animals. In 1956, at an AEC-Department of Defense (DoD) symposium, Cohn reported on the persistence of radioactive contamination of both land and marine animals two years after Operation Castle (Cohn 1956). Some native rats were added to the roster of animals already mentioned. The difference in relative importance of elements like zinc and cobalt in the marine forms compared to the terrestrial forms began to be very apparent in this work.

At the same symposium on the hazards of fallout, H. V. Weiss, also from NRDL, showed figures for many plant species, as well as animals. There were wide differences among plants, e.g., portulaca was many times more active than other plant species from the same place. However, there were enough differences between individuals to promote caution in making generalizations. About all that could be said was that predictions of possible intake by humans of fallout deposited on or in plants would require many specimens and much averaging. The islands as a whole were fairly consistent in the average amount of activities in plants. Soil activities showed the same trends, i.e., by the end of two years the amount in plants correlated well with that in soils, a situation that does not hold at early times because of foliar deposition. The primary contaminant in coconut, papaya fruits, pandanus, and arrowroot tubers was ^{137}Cs , plus significant amounts of rare earths in papaya and arrowroot tubers. Strontium-90 was in low concentration in all of these edible plant materials by the end of two years. The leafy structures had much more of the rare earths than of ^{137}Cs ,

(a) Dr. Stanton Cohn, who spearheaded much of the collecting and the work at NRDL, finally got an opportunity to try out the decorporation agents, EDTA and zirconium citrate, that he had originally been ordered to take with him to the Pacific (see p. 897). Eight chickens with relatively large body burdens did excrete more beta-active radio-nuclides during treatment, but the increase in rate was not sufficient to reduce the body burdens significantly (more in chapter 19).

illustrating again that the fallout radionuclides are far from uniformly distributed in plants. A summary of a few of these data is shown in table 12.6, taken from the paper by Weiss (1956).

TABLE 12.6. Average Relative Composition of Nuclides in Plants, Soil, and Water
— Marshall Islands —

Source		Number of Samples Averaged	Relative Composition (percent)			
			Cs ¹³⁷	Total Rare Earths	Sr ⁹⁰	Ru ¹⁰⁶
Plant:	Part	Plants				
Portulaca	Whole	1	48.9	39.2	11.8	
Papaya	Fruit	1	79.8	17.8	2.5	
	Husk	3	98.2	1.1	.7	
	Meat	2	98.9	.05	1.0	
Coconut	Shell	2	99.5	.4	.1	
	Milk	1	99.6	.2	.2	
	Leaves	2	8.3	86.5	.4	5.1
	Keys	2	92.6	2.2	5.5	
Pandanus	Leaves	2	72.7	13.3	5.1	8.9
	Air root	2	88.9	10.3	.8	
Arrowroot	Tuber	1	75.4	16.8	1.0	6.8

More details on the internal contamination of animals can be found in the second AEC report (Dunning 1957a). Considerable emphasis is placed on the large decrease in gross activity with time of all objects, animate and inanimate. Decreases of two orders of magnitude over a six-hundred-day period were quite characteristic, as might be expected. (See, for example, Dunning 1957a, p. 6-7.)

Of special interest to possible long-term survival of animal life after extensive fallout contamination is a study by the group from the Applied Fisheries Laboratory and later the "Eniwetok Laboratory." This concerned the rats of Enjebi, a highly contaminated island. We can tell the story best by excerpts from Hines's description of the work:

The question concerned the colonies of rats on Engebi Island. Periodic sampling and observation of the Engebi colonies had been conducted, by 1955, for more than six years, a period in which Engebi had been the site of two atomic shots, within the radius of destruction of two thermonuclear detonations, and the scene of repeated and extensive engineering operations incidental to testing. The twelve months of continuous work in the Pacific after Operation Castle had provided,

however, the first opportunity for consistent and detailed observations of the rats as residents of Engebi. In view of the known experience of Engebi Island as a nuclear test platform, the question now arose insistently as to how the rats had been able to survive repeated nuclear blasts and to continue to rebuild their numbers in a radically altered and frequently highly irradiated environment.

Few spots on earth had been exposed to more prolonged periods of violence than Engebi. In the years between 1944, when the island had been subjected to preinvasion bombardment, and 1954, when it felt for the fourth time the impact of nuclear detonation, Engebi's 250-acre triangle had become a barren, sandy plot from which the coconut palms and other trees had long since disappeared and on which the most significant features were man-made structures, including the great reinforced concrete building that had survived the pressures from the Mike shot on Elugelab in 1952. From 1948 to 1952, Engebi had been a principal collecting area for rat specimens, even though the island had been the site of the early atomic detonations in 1948 and 1951. After the Mike shot, the search for rats had extended over Engebi, Biiijiri, and Rojoa Islands, but only on Biiijiri, nine miles from the point of explosion, had specimens, weak and ill, been found. Engebi was much nearer than Biiijiri to the Mike site (the center of the island was 3.2 miles from ground zero), and the low terrain had been exposed to a sequence of forces which included thermal radiation, initial nuclear radiation, shock, water waves, and residual nuclear radiation. Members of the Laboratory group, inspecting Engebi briefly a week after Test Mike, had seen the effects of these forces and had encountered beta-gamma radioactivity at a level of 11 roentgens an hour. No living animals except the transient birds could be found, and thus they had reported that there was "little probability that any rats survived on Engebi." But while it may have been unreasonable to expect that rats had survived, some had done so. Furthermore, rats survived the Nectar test of 1954, when a device detonated in the Mike crater had sent another surge of contaminated water over Engebi. By 1955, grass and scrub vegetation was sprouting on the island again, and in this new cover colonies of rats were establishing new runs and burrows. The colonies were being rebuilt even though the population had been subjected not only to physical shocks of unprecedented force but to amounts of radioactivity sufficiently high to cause the early deaths of individual survivors and genetic changes in offspring. . . .

Residual nuclear radiation levels following the Mike shot were very high. Animals aboveground would have received 2,800 to 6,700 roentgens during the first hour and those in the burrows 112 to 1,120 roentgens. During the first nine days following detonation, rats in burrows received 250 to 2,500 roentgens of total integrated dose. Cumulative levels probably were higher as a result of radioactive materials being washed into the burrows by the surge of water from the Mike crater, and the percentage of rat survival probably was extremely low. Because the Nectar device of 1954 was detonated over the Mike crater, water was lifted into the column and both thermal and residual nuclear radiations were of lesser effect. The total integrated residual nuclear radiation dose for the center of the colony a week after the Nectar detonation was 65 roentgens of gamma and 290 roentgens of beta-gamma activity. Animals in the burrows, it was calculated, would have received a maximum of 55 to 80 roentgens of beta-gamma if they stayed in the burrows for most of the week. Several animals collected nine days after Nectar had beta burns as well as thermal burns, however, and even during the later visits to the island it was not uncommon for members of the Laboratory staff to collect living rats on which losses of patches of fur and searing of the flesh testified to their exposure to sources of residual beta radioactivity. . . .

Studies of the effects of internal exposure of the rats were conducted by Lowman at the EMBL [Eniwetok Marine Biological Laboratory] and, later, at the University laboratories. Radioactive materials had entered the bodies of specimens, he found, by inhalation, by ingestion of contaminants in water and food and on the fur, and through open wounds. Iodine 131 appeared to be the principal isotope gaining

entry by inhalation. After the Nectar detonation concentrations in the thyroid were at levels considered excessive, but specific radioactivity in organs and tissues changed with time and within nine weeks activity in the thyroid was so low that measurement was difficult. The day following detonation of the Nectar shot, specific activity of the skin was just below that of the thyroid, with activity still lower in the gut, bone, lung, kidney, muscle, and liver. Within five weeks, however, specific activity was greatest in the bone of random specimens and continued to be so for the remainder of the year. Chemical separations, decay curves, and absorption curves indicated that most of the radioactivity in muscle was due to the presence of cesium 137, and no strontium 89-90 was found in that tissue. In bone, however, isotopes included rare earths (approximately 20 per cent), small amounts of zirconium and niobium, and strontium 89-90 at a level of about 10 per cent of the total activity present. In January, 1955, the bones of rats contained strontium 89-90 in amounts approximating the maximum permissible dose, but no bone tumors had been discovered and none was found in specimens collected later. In general, the deposition of radioactivity within the bodies of the rats followed familiar patterns. In a report in May, 1955, Lowman said: "In view of the fact that this population had been subjected to high levels of radiation capable of producing genetic effects in the survivors as well as early deaths of others, observable effects upon the present inhabitants should have occurred. However, the pregnancy rate and the average number of embryos per litter do not vary significantly. . . . The sex ratio does not vary from a 50-50 ratio. Except for those taken shortly after detonation, almost all individuals examined during the last year appear to be in good physical condition. . . . In addition, the main colony is expanding both in numbers and in occupied area."^(a)

The bearing of these findings on possible survival of other populations exposed to heavy fallout requires study. The behavior of fallout radionuclides in marine biota as determined during the earlier studies of the 1950s has been reviewed in previous sections.

A useful summary of the radionuclides identified in a number of life forms and in soil and ground water from the work at Rongelap Atoll in the 1950s is given in figure 12.11.

b. Postlude

The level of activity in biological and ecological research naturally decreased markedly after the cessation of tests at the Pacific Proving Grounds. Nevertheless, the biologists were firm in their resolve to get as much of the long-term picture as possible. Thus, the medical return visits were almost always accompanied by some people who took samples of water, food, and general biota. Some of the work came from expeditions concerned more with worldwide fallout than specifics of the Pacific Proving Ground. Yet, the efforts were mutually helpful.

A considerable stimulus to further research at the Proving Ground was the continuing concern over repatriation of the Marshallese described earlier. In 1963, a Biomedical Research Program was established at LLL (chapter 13). Its primary charge was to study the effects of early fallout. On request from Washington, the LLL people went deeply into analyzing the health risks of resettling the atolls. They mounted a comprehensive analysis of the radionuclides present, their transfer within the environment, and from the environment to food. They looked especially at what exposures might result from eating crops raised on the islands, drinking the water, or eating fish caught from the lagoon.

^(a) Hines 1962 (pp. 206-207; 210-213), who quotes from Lowman 1955.

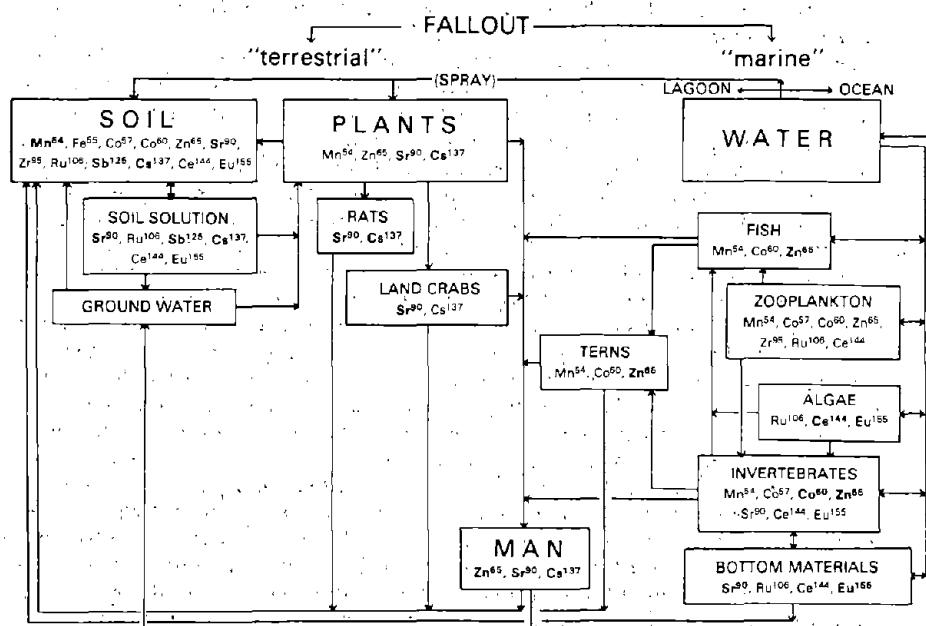

FIGURE 12.11. Distribution of fallout radioisotopes at Rongelap Atoll, 1959. The more important (i.e., dominant) radionuclides are indicated in bold type within the groups. Note that the terminology of the day is used. (Reset from Hines 1962 using data by Held; Reprinted with permission of University of Washington, Seattle, Washington, copyright 1962.)

As frequently occurs when a new organization enters a field, the people from LLL acted as though nothing was known before.^(a) While this was not true, as we have already seen (check for example figure 12.11), there is no question that much more was known when their studies came to maturity. The level of sophistication was also increased to include large data banks and computer models for dosage estimation. A new feature was consideration of the role of residual plutonium and other transuranics. We will review some of the pertinent work in the decades since 1960 as cryptic listings:

1. At the first Radioecology Symposium (chapter 11) Lowman (1963) of the Puerto Rico Nuclear Center, reported on the radioactivity of tuna and plankton from the Central Pacific. The contamination came largely from the Hardtack I series in 1958. The tuna specimens, over one thousand of them, were obtained from fishing vessels landing at Japanese ports.^(b) It appeared that three factors controlled the uptake of radionuclides from sea water:

(a) "When we began there were no data on inventories of radionuclides in soils and water. Nothing was known about their movement from one part of the environment to another. . . ." From brochure on the LLL Biomedical and Environmental Research Program (undated).

(b) Dr. Toshihara Kawabata (National Institute of Health, Tokyo) was instrumental in providing the fisheries' samples to Dr. Lowman.

isotope dilution by the corresponding stable element; complex formation between divalent cations and biological materials; and the metabolic requirements, or lack of them, for certain elements. Uptake patterns at three trophic levels, plankton, omnivorous fish, and the carnivorous tunas, showed clear evidence of discrimination for or against certain radionuclides.

2. A careful study by Held (1963), University of Washington, of the qualitative distribution of radionuclides at Rongelap over five years after fallout contamination indicated that ^{90}Sr , ^{125}Sb , and ^{137}Cs were the principal nuclides entering the soil. However, in land plants and plant-eating animals, ^{137}Cs was the highest, with ^{90}Sr in lesser concentration. The marine organisms continued to show the entirely different cadre of radionuclides as described in the previous section of this chapter. Also, it was different in different groups, i.e., plankton versus algae versus marine invertebrates versus fish and sea birds. It became quite clear that the body burden of any humans of the area would be very dependent on the diet qualitatively as well as quantitatively.
3. A description by Welander (1969), University of Washington, expanded on the distribution of radionuclides in the environment of Enewetak and Bikini Atolls. This was expanded upon further by Jackson and Carpenter (1969), with a description of radioisotope cycling in terrestrial communities at Enewetak Atoll.
4. Later work by Held (1971) and others used tuna from the Japanese fisheries and from the vicinity of Bikini and emphasized the increasing role of ^{55}Fe in light and dark muscle and in liver. It was suggested that some of the ^{55}Fe came from USSR tests of 1962 and was deposited in narrow bands related to the test sites at 75° and 52° N, since specimens from the southern hemisphere were much lower. Held references several other studies involving ^{55}Fe . Interestingly, the concentrations of ^{137}Cs were found to be about the same as those reported in the 1960s (Seymour 1963a; Folsom and Young 1965). Yellow fin tuna from Bikini Atoll contained ^{60}Co believed to have been derived from the atoll. As before, the catches re-emphasized the large variability that can be encountered in specimens with no obvious reasons for a difference.
5. More work on ^{55}Fe was published by Schell in 1975, which emphasized especially the partition among water, suspended particles, and colloids. Schell believes that the primary source of this ^{55}Fe was the barges used to hold the fission devices in the lagoon and the iron buildings that housed the thermonuclear devices on the atolls. He cites the large concentration factors for iron by phytoplankton (25,000) and zooplankton (15,000) and the significant transfer of ^{55}Fe through the food chain. No work was done to show possible biological effects, but it is significant that despite the "70-fold decrease in radioactivity by decay since the last nuclear detonation at Bikini in 1958, some sediments contain concentrations of ^{55}Fe as great as 300 pCi/g dry weight" (Schell 1975).
6. Data on ^{137}Cs and ^{60}Co in soils, plants, and rat tissue samples were collected on Runit, one of the more contaminated islands. These were presented by Bastian and Jackson (1975) from Bowling Green State University in Ohio. The amounts in animal tissue ranged between 0.5 and 500 pCi/g, in plants between 2 and 200 pCi/g, and in soil (the first 50 cm) between 0.1 and 2 pCi/g. Obviously, the living tissues were able to concentrate the nuclides from the soils. The data agreed well with AEC information, but note the very large ranges.

7. There was a long series of studies from the LLL Some of these are:(a)
- a. *Dose Estimates for the Marine Food Chain* by Robison (1973)
 - b. *Terrestrial Biota Survey at Eniwetok*, by Koranda et al. (1973)
 - c. *Radioactivity Levels in Enewetak Soil*, by Gudiksen and Lynch (1975)
 - d. *Transuranics and Other Radionuclides in Bikini Lagoon: Concentration Data Retrieved from Aged Coral Sections*, by Noshkin et al. (1975)
 - e. *Evaluation of Plutonium at Eniwetok Atoll*, by Wilson, Ng, and Robison (1975)
 - f. *Plutonium Levels in Kwajalein Lagoon*, by Noshkin, Eagle, and Wong (1976)
 - g. *Evaluation of Water Quality*, by Noshkin et al. (1977)
 - h. *Plutonium Concentrations in Fish and Seawater from Kwajalein Atoll*, by Noshkin, Wong, and Eagle (1979)
 - i. *Transuranium Radionuclides in Components of the Benthic Environment of Eniwetok Atoll*, by Noshkin (1978, 1980)
 - j. *Reassessment of the Potential Radiobiological Doses for Residents Resettling Eniwetok Atoll*, by Robison et al. (1980)
 - k. *Radionuclide Concentrations and Dose Assessment of Cistern Water and Groundwater at the Marshall Islands*, by Noshkin et al. (1981)

There is no doubt that even now (1985) the lingering contamination on these atolls and islands with cesium and to a lesser extent, strontium, is a major obstacle to the much desired resettlement of the several Marshallese populations. We will see details in other connections. Suffice it to say here that the measurements must be continued. Also, let it be emphasized that some extremely embarrassing mistakes, in terms of both health effects and political interrelationships could have occurred if the researches described in the previous pages had not been taken seriously and continued at a significant level. There is no indication that we are yet "out-of-the-woods." What may seem to many to be a never-ending enterprise has proven its worth and the need for its continuation. Also, the research results have contributed and continue to contribute significantly to our knowledge of the movement of radionuclides in the environment, particularly the role of "recycling," as we will see in chapter 15.

The work on the transuranics requires comment. It appears that the lagoon water, most of the time, contains concentrations of $^{239+240}\text{Pu}$ (and ^{241}Am) similar to concentrations from global fallout. Yet, samples of fish in 1972 contained considerably higher concentrations. This work predicted elevated concentrations in humans, if the reef species of fish were eaten regularly, of 25% of the radiation protection guide (RPG). Later work indicated that the 1972 collections of fish had unexplained high concentrations of transuranics and that there was probably some mistake. The 1979 work (Noshkin, Wong, and Eagle 1979) showed much lower concentrations in fish and resulted in a calculated dose rate from the marine pathway of only 0.005% of the RPG.

On the terrestrial side, there were local areas of high plutonium concentration. But the average was well within even the new Environmental Protection Agency (EPA) limits. Nevertheless, it was clear that the local "hot spots" would have to be cleared up before anyone could move back for regular living on

(a) These are only samples. There are many more on the same general subjects in UCRL reports.

some of the islands. As a recap of the many findings regarding the biota at the Pacific Proving Grounds and the problems solved regarding fallout contamination, we turn to a summary prepared by Hines (1962). While this does not address the most recent work and says nothing about the transuranics or problems of repatriation, it stands as a good review of the landmark research findings. It considers the thrust of the biological and environmental work in the Pacific from Crossroads to the cessation of testing.

It was known, for example, as it had not been known in 1943 and as it had been realized only faintly in 1946:

- that in the natural environment the extremely efficient biological uptake of nutritive elements can be measured in the uptake of the radioactive counterparts of such elements;
- that the levels of uptake of radioactive elements by the biological organism will be affected by the character of the organism — its physical complexity, its mineral needs, its metabolic processes — and by the chemical and physical form of the radioactive isotopes, the availability of stable isotopes, and the conditions of the environment;
- that radioactive elements, because they are identifiable, can be followed through food chains and biological systems virtually to the limits of their detectable lives, and that studies of elements in nature thus can be pressed much further than previously had been considered possible;
- that in aquatic environments the basic organisms, such as those comprising the masses and plankton and algae, not only are more resistant to the effects of radioactivity but are capable of blotting up quantities of radionuclides and thus placing them at the threshold of the biological system;
- that in the natural environment the circulation of radioactive elements involves both water and land, and that between the two there will be environmental transfer, some “uphill” from water to land and some “downhill” as elements are rinsed or leached from soils or plants and carried to the rivers or oceans;
- that products of nuclear fission, significant on land, are far less so in sea water, and that, on the other hand, the nonfission products such as radioactive forms of iron, cobalt, manganese, or zinc may contribute up to 100 per cent of the radioactivity found in aquatic organisms, from the plankton and algae to the larger fishes;
- that radioisotopes introduced in large quantities into the ocean (either by initial mixture in an underwater release or by fallout after an atomic explosion) are transported both by ocean currents and by ocean organisms, but that the physical movement will be affected by the biological conditions and modified by biological rules and processes;
- that masses of radioactively tagged water may be followed and measured across thousands of miles of ocean, much farther and longer than had been supposed possible before 1954 and 1955;
- that strontium 90 and cesium 137, among the long-lived radioisotopes of greatest public concern, are found only in low amounts in marine organisms studied under field conditions, and that the radioisotopes found in fish, for example, are predominantly the shorter-lived nonfission products elements such as iron, zinc, or manganese;
- that certain biological species, because their physiological needs are known and their places in the food chains established, may be used as reliable indicators of the nature and probable extent of the radioactive contamination of a natural environment at any point in time;
- that populations of animals and plants observed under field conditions—the sea urchins of Bikini in 1947, the grasses and shrubs restoring the natural cover of Eniwetok’s shot islands, or the rats of Engebi — exhibit a capacity to maintain themselves even in environments that have been exposed to the full effects of nuclear blast and to levels of radioactivity that all laboratory experience indicated were totally lethal;

—and that every release of radioactive products in nature whether by atomic detonation, by accident, or in the disposal of industrial wastes, sets up a biological reaction peculiar to the place and condition of the release itself; that the variables are almost infinite in number; and that the individual situation can only be assessed by conducting observations with a knowledge of the biological rules governing the disposition of radioisotopes in the natural environment.
(Hines 1962, pp. 306-307)

The above can be considered as among the “knowns” worked out in research at the atolls. Among the many unknowns is the *ultimate effect* on biota of fallout of the magnitude experienced in the Marshall Islands. While the resiliency of nature was demonstrated on many occasions, vast areas of oceanic radiobiology remain essentially unknown. These can be studied profitably only by an organized and well-financed attack.

IV. Trinity Revisited

In the summer of 1945, after the shot at Alamogordo (section II A), the Los Alamos people revisited several suspect houses and barnyards and gathered evidence that the Chupadera Mesa area had remained “hot.” However, the pressure of other things (e.g., Crossroads) prevented further follow-up until August 1947. At this time, a combined survey team of biologists and chemists from UCLA and the University of California, Berkeley, under the supervision of Wright Langham from Los Alamos, spent three weeks working over the area. They were able to cover about one hundred square miles. The results were issued in a classified report in several sections covering soils (Overstreet et al. 1947; Overstreet, Jacobson, and Larson 1947), botany (Dunn and Levine 1947), ornithology (Van Rossem 1947), mammals (Brauner 1947), herpetofauna (Lowe 1947), and entomology (Mattoni 1947).^(a) The results of this survey indicated several interesting facts:

1. Residual radioactivity was definitely present in the grasses and was found in cattle feces.
2. The activities were definitely higher in some of the more distant areas than close to ground zero.
3. There had not been much leaching down of the soil activity. It had remained in the first centimeter or so near the surface. Since most of the desert plants have fairly deep roots, the fission products had not been taken up to any appreciable extent from the soil. The exception was the shallow-rooted grasses, but much of their activity might have been surface deposition.
4. No signs of radiation injury were seen in the animals collected.
5. Some plants were growing back in the center of the crater, evidently from underground roots and windblown seeds. There were practically none toward the periphery of the crater, which gives the idea that the temperatures may have been higher there than in the center.
6. One region of high activity, the Chupadera Mesa (see section I A), was being used extensively for cattle grazing. Calculation indicated that a

(a) I am indebted to Jack Healy, Los Alamos, for making available copies of these reports, which he had obtained in turn from Pat Durbin at Berkeley. They were in Joe Hamilton's files since he sponsored the Berkeley contingent of the survey team.

- 1,000-lb cow might ingest as much as 600 μ Ci per month or 7.2 mCi per year of fission products, and this was based on present, not earlier, activities. This caused considerable concern.
7. There was no evidence of genetic change in animals, plants, or insects; not surprising in view of the times needed for mutations to be expressed.
 8. The area covered by the fallout was obviously much greater than suspected from the survey in July 1945.
 9. It was conjectured that the "hot" area on Chupadera Mesa was the result of several phenomena: (a) the initial cloud hovered over the ground zero and adjacent areas during the morning hours because there was very little air motion; (b) as the day progressed, the usual thermal breeze started and the cloud began to move; and (c) the characteristic midafternoon summer thunderstorm washed out the cloud over the mesa and deposited an appreciable portion of its activity.
 10. There were many puzzles with regard to distribution of the fallout, the transfer into and about the biome, and the characteristics of the repopulation forms and processes.

It is unfortunate that these reports, while declassified in March 1972, have never been published. They are full of detail and replete with maps and illustrations.

In 1947, Stafford L. Warren, the medical director for the MED up to its disbanding, instigator of the Columbia River surveys (chapter 11), and caretaker of the safety of Operation Crossroads (section II-C of this chapter), settled at UCLA as director of the newly organized Atomic Energy Project of UCLA and as dean of the new medical school about to be built. He maintained his keen interests in the problems of fallout and the biomedical aspects of weapons testing by proposing to AEC further visits to the Trinity site. In a long letter to Brigadier General James McCormack, Jr., AUS, Military Application Division, USAEC, he pointed out the growing tendency for use of that land for cattle grazing, the digging of wells, and other reasons to know what was there. He suggested several summer surveys using graduate students and other individuals with lowered commitments in summer and a permanent organization to guide and interpret the effort. The enterprise was approved and, naturally, the permanent organization chosen was the UCLA Atomic Energy Project! Thus began a decades-long association of the project with the weapons-testing program, especially in the area of terrestrial phenomena. The collaboration with Los Alamos continued, particularly for doing the radiochemistry and for continuing opportunities to tap the deep Los Alamos experience in people like Wright Langham and Thomas Shipman.

Since Warren was busy building a medical school, the work had to be carried forward by staff of the project. Chief among these was Kermit H. Larson, the rest of whose career was devoted to understanding what went on at the test sites. J. H. Olafsen, J. L. Leitch, A. W. Bellamy, E. M. Romney, and many others were also included.

The efforts toward further survey of the Trinity site were contained in UCLA project reports (Overstreet et al. 1947; Bellamy et al. 1949; Leitch 1951; Larson et al. 1951a, b; and Olafsen et al. 1957). As the report titles indicate, the emphasis changed gradually from the fission products to plutonium and the actinides, as occurred also at the Pacific Proving Grounds.

These researches became the basis for the UCLA Laboratory's assessment of contaminated landscapes in general. They showed clearly the irregular patterns

of fallout deposition and the presence of what appeared to be "hot spots" like the Chupadera Mesa.^(a) The amounts of activity in mammals did not correlate with dose-rate patterns put down for the fallout contours. Soil properties and the chemical nature of the fallout materials played an important role.

Toward the end of the revisits to Trinity, it became very hard to measure any activities above background for the fission products, so attention turned to the long-lived actinides.^(b)

In general, the findings confirmed the earlier work. There was no doubt that the radioactivity outside of the crater increased with distance out to as much as eighty-five miles. The maximum occurred at about twenty-eight miles from ground zero, and the activity then decreased but was easily measurable out to eighty-five miles.^(c) This was true of soil (surface layer only) and of both animals and plants. Even after many years and scores of rainstorms, activity deposited on the leaves of some plants was almost impossible to remove.

Interestingly, the concentrations in animal tissues that were very low in the first two years began to be detectable in 1949 and 1950 in, for example, the pack rat. There was activity in liver and bone as well as in the digestive tract. Activity in plants rose similarly but somewhat earlier. These data point to some sort of accumulation process. Was the material being solubilized and thus becoming more available? Laboratory work has been directed toward this point, as we will see in chapter 13. It shows that solubilization processes can take place and that the chemical form of the isotope may not be constant over time. It is also interesting that considerable variation in chemical form can occur, even in a relatively circumscribed area like the Trinity site.

Relatively little of the early UCLA work on Trinity has been published in the open literature except for plutonium work.

Even though the people at Los Alamos had pioneered the environmental work at Trinity, they were too occupied with the Pacific and problems of worldwide fallout (sections III and IV) to do much more than help with the August 1947 resurvey. However, they did re-enter the field for determination of environmental plutonium at the Trinity site at twenty-seven and twenty-eight years after the event (Hakonson and Johnson 1974; Nyhan, Miera, and Neher 1976). Both of these efforts concentrated on soil contents and the behavior of plutonium in soil, but they included also samples of grasses, shrubs, and trees, and of rodents. Some of their data are shown in table 12.7.

These data indicate that amounts of plutonium do indeed seem to be higher at certain points along the fallout pathway. Note, for example, the relatively high values in the top section of soil as far out as 40 and 56 km and the apparent concentration in lungs of rodents at 32 and 40 km compared to even 0.1 and 48 km. (Is there a special area for dust inhalation?) Also note that grasses are consistently higher than forbs, shrubs, or trees. Indeed, all of the vegetation but the grasses was essentially at background levels.

(a) Later work has called into question some of the hot spots indicated in earlier work at the Nevada Test Site (NTS), but the presence of "Hot Canyon" and Chupadera Mesa as hot spots has held, as have the probable reasons for their existence.

(b) Larson (1979) emphasizes that only a small fraction of the plutonium in a fission device is consumed in the detonation. Most of it is carried aloft and can be distributed over wide areas.

(c) This raised questions as to whether or not the surveys should be expanded to a considerably larger area.

(a) Twenty-seven to twenty-eight years later.

Source: Reset from Hakonson and Johnson 1975.

Comparison with earlier samples indicated that the plutonium had finally, after twenty-seven years, gone down into the soil to at least 30 cm, whereas in the earlier resurveys it seemed to be fixed in the uppermost layer. This process was not so marked at distances beyond about 24 km. The gross distribution after twenty-seven years indicated some increased migration of plutonium but basic agreement with the UCLA findings many years before.

The twenty-eight-year survey did size-activity analyses. There was more plutonium associated with small particle sizes (less than 100 μm) at greater distances from ground zero and as soil depth increased. Neither is surprising, of course, but such factors have an important bearing on possible availability to biota.

Finally, the Los Alamos workers, Hakonson and Nyhan (1980), produced a comprehensive summary of plutonium distribution at Los Alamos compared to Trinity. This was in Hanson's book, *Transuranic Elements in the Environment*, described in chapter 11. Concentration in herbaceous vegetation was related to that in soils from all sites and is believed to indicate external contamination rather than uptake through the root system. Certain rodent tissues also correlated well with soil plutonium, and most of the plutonium was associated with pelt and gastrointestinal tract in the native rodents. This again indicates a dominance of "physical processes" (e.g., ingestion of dirt, dust on the pelt,

inhalation of dust) over metabolic processes. There was no evidence for increase in plutonium concentration as it passes through different trophic levels, i.e., soil to vegetation to animal. About the only difference between Los Alamos and Trinity was the dominance of water as a transport vector at Los Alamos and of wind at Trinity.

The experiences gained in the resurvey of the Trinity site provided excellent background for what was to come at NTS. In fact, the work could be more unified and uncomplicated because there were no other tests occurring to deny access to important areas, or to introduce the complexities of new fallout to confuse identification and measurement of the samples. Obviously, the Trinity resurvey was largely a Los Alamos and UCLA show.

V. The Nevada Test Site

A. The Arrangements and Events

The decision to open a site for testing of nuclear weapons in the continental United States was partly a result of the Korean War. The logistics of supporting the Pacific Proving Ground were strained by the need for naval vessels and planes in the Far East. Also, the Cold War was developing. The pressures to perfect devices without the long trek to the Pacific spurred Los Alamos to urge a quick program to check design revisions at a site nearer to the laboratory. Also, the need for a more or less permanent test site for the "small" weapons further spurred agitation for a continental test site.

The Air Force had for many years maintained a very large bombing and gunnery practice range over an area in Nevada beginning about fifty miles north of Las Vegas. After many studies during summer and fall of 1950 (Hacker, undated), President Truman approved the choice of a portion of that area as a nuclear-weapons test site. A base camp was set up at a spot designated as Mercury, and the tests were spread out over a vast area, largely north and northeast of Mercury. Mercury, which developed from a tent city to a reasonably comfortable complex of workshops and barracks,^(a) is about seventy miles from Las Vegas, the test sites from twenty-five to over fifty-five miles further along. Gradually, facilities for biomedical work were developed at Mercury. These started as holding quarters for mice and rats, but eventually expanded to accommodate pigs and burros among other large animals. The Army and Air Force Veterinary Corps played active roles in operating these facilities.

At the time of this writing, 569 announced shots had taken place at NTS under U.S. auspices plus 13 under joint U.S.-U.K. auspices, for a total of 582 (NVO 1982). Comparison to the total of 106 shots in the Pacific makes it appear that NTS overwhelmed all others. This was true only in terms of numbers of tests.

The atmospheric tests occurred in eight series: Ranger, winter 1951; Buster-Jangle, fall 1951; Tumbler-Snapper, spring 1952; Upshot-Knothole, spring 1953; Teapot, spring 1955; Redwing, spring and summer 1956; Plumbbob, spring,

(a) To compensate for the alternate tedium and pressure of life away from families, assigned military and hoards of engineers could get food at Mercury that was excellent and cheap. One of the ubiquitous silver dollars in a turnstile opened up an all-you-could eat, cooked to order, mountain of food. After a full day in the field, some prodigious appetites were generated and indulged.

summer, and fall 1957; and Hardtack, Phase II, fall 1958. A few of these were underground. In 1961 and beyond, all tests were underground. A large majority were weapons-related or concerned weapons effects (e.g., the Civil Effects Test Group work, which involved effects on animals and on structures). A few involved the placement of troops, the reverberations of which are now very strident. Twenty-seven were Plowshare shots and thirty-three were designated as "safety experiments." Since the purpose of the tests, except the Plowshare and safety shots, do not make much difference to the thrust of our discussion, we will not tie the discussion to specific events except for identification purposes. The Plowshare and safety shots are "special events" and will be considered in chapter 14.

While there is no question that large quantities of fission products reached the atmosphere from Nevada, many shots were relatively small. Some of them were on the order of 1 ton of TNT equivalent, although a goodly number were in the kiloton range, even as high as 43 kt,^(a) twice the yield of the "nominal" Hiroshima and Nagasaki weapons. Of the total NTS shots, only about one hundred were in the atmosphere. Nevertheless, the total contribution of these to atmospheric contamination was considerable; much of it was to the troposphere, whereas the Pacific tests nearly always had stratospheric as well as tropospheric components. Thus, the NTS work contaminated our own real estate more than others, while the Pacific activities contributed much global as well as highly active local contamination.

It has been estimated (Perkins and Thomas 1980) that about 230 megatons of fission yield were introduced into the atmosphere from all above-ground tests. The contribution of the NTS is given by Larson (1963) as about 101.3 kt up to 1961 when he wrote the paper.

Although the external dose was the primary measurement, the potential for radionuclide contamination was not lost on the UCLA and associated investigators. They, particularly Kermit Larson and E. M. (Van) Romney with or without assistants, tramped around the desert as much as possible between shots and during lulls between series to collect samples of soil, vegetation, and indigenous animals. They were sometimes joined by ecological types from other installations. We will be reviewing this work in due course.

The early RadSafe activities at NTS^(b) were provided by the Health Division (H-Division) of Los Alamos Scientific Laboratory. When Dr. Shipman, the medical director at Los Alamos, began to complain about the emptying out of his H-Division whenever tests were in progress at either NTS or in the Pacific, other AEC laboratories were tapped to supply scientists who could help out.^(c) After a quick training period, these "volunteers" were largely put into the job of mapping fallout patterns. In the interim, the responsibility for these operations had shifted from Los Alamos to UCLA, and Kermit Larson became something of a steward for the RadSafe activities, as well as others we have already discussed.

(a) Even larger ones were employed for some of the later underground shots.

(b) An extensive review of the RadSafe activities at NTS, series-by-series, will be available from Hacker. See also Dunning (1957b).

(c) All laboratories had their innings as they did for Operation Crossroads. While there was some attempt to tap special abilities, much of the work was assigned in more or less military fashion. Thus, Lauren Donaldson (see chapter 11) drove trucks, and most specialists acted as monitors. Some formed deep attachments to the desert. Others could barely wait to get home.

The military, of course, supplied much manpower, and collaboration between the military and AEC and was, of course, essential.

A short summary of the safety measures taken at NTS is given in the following from a paper prepared for the 1963 Congressional hearings and submitted by A. R. Luedecke, General Manager of AEC:

Safety at the Nevada Test Site

(By Division of Operational Safety, U.S. Atomic Energy Commission, June 13, 1963)

The health and safety of persons was, and has been, the prime considerations in selecting originally the Nevada test site and in the conduct of the nuclear tests. An exhaustive search was made before the Nevada site was selected as the most suitable one. It originally contained 600 square miles (expanded to about 1,120 square miles) adjacent to the U.S. Air Force Gunnery Range of 4,000 square miles. For purposes of general safety, as well as security, the test site is closed to the public. Aerial and surface surveys are made to insure that no one has wandered into the area.

Beyond these controlled areas are wide expanses of sparsely populated land, providing optimum conditions for maintenance of safety. Although the area is only sparsely populated the individual resident has been given full consideration. Radiation monitors have been present during times of testing and there have been occasions when residents have been relocated for a day or so to insure their safety. They have received financial remuneration for such movements. There have also been occasions when persons have been asked to remain indoors for a few hours to reduce the radiation dose though the out-of-door exposure was far from hazardous.

Before each and every nuclear detonation at the Nevada test site, a panel of experts weighs carefully all of the factors that will insure safety. On the panel are representatives from the fields of public health, medicine, meteorology, fallout phenomenology, blast effects, etc. As a result of these deliberations, more than 200 delays in firing have been made at a cost of millions of dollars, to insure safety.

The principal cause for the delays has been weather conditions, i.e., to insure minimum fallout in populated areas. A complete station of the U.S. Weather Bureau is in operation at the site with one to eight weather monitoring stations ringing the test area depending upon the type of test to be conducted. The U.S. Weather Bureau predicts downwind trajectories, precipitation, and other factors which could affect levels of fallout. The data from the weather stations are currently available almost up to the exact time of the shot. A detonation can be canceled at any time up to a few seconds before shot time. All of the meteorological data bearing upon each test are documented not only for the Nevada test site but for the entire Western United States.

(From U.S. Congress, 1963, Part I, p. 294)

This statement was referred to later in the hearings by Glenn T. Seaborg, then AEC Chairman, as typical evidence of the care taken by AEC to protect the nation's health during the tests.

It will be noted that a panel of experts (The Test Managers' Advisory Panel) was convened before each test to advise the Test Director on matters of safety. This was a senior and powerful group. Not mentioned in the quotation is the fact that the U.S. PHS usually had a representative present, and he had a powerful voice in the decision to shoot or not to shoot (Andrews 1980). This was important because the PHS was there exclusively to protect health and had none of the dilemmas some of the others had of needing the weapons data, of making people repeat the countdown operations, or of holding a group of reluctant scientists and military in a desolate and primitive environment.

Offsite surveillance was rather rudimentary in the early days. Indeed, as we will see in the next section, the extent of offsite contamination was not fully appreciated. As the need for good offsite surveillance became apparent and grew, the PHS was drawn in under contract to AEC and provided what became an extensive network. This was continued under the auspices of the EPA, which took over the network and laboratories built up by the PHS. A further short excerpt from the 1963 Congressional hearings addresses this aspect:

Full monitoring coverage has been provided offsite by the U.S. Public Health Service under contract with the U.S. Atomic Energy Commission. There have been and are extensive monitoring programs, including mobile monitoring teams, film badges, air samplers, automatic gamma recorders, collections of milk, vegetation, soil, etc. A more complete description of these programs may be gleaned by review of the attached document, "Environmental Contamination From Nuclear Explosives Offsite Nevada Test Site, September 15, 1961-September 15, 1962." The cost of these monitoring programs is about three-quarters of a million dollars per year. In addition, there are various research projects that contribute valuable information.

All of the essential data from these monitoring programs have been reported in the open literature. The principal sources for publication have been the Commission's semiannual (now annual) reports to Congress and the U.S. Public Health Service's monthly publication, *Radiological Health Data*. Spot announcements have been made of immediately available data. Also, members of the Commission's staff have published many technical articles presenting data and their analyses.

(U.S. Congress, 1963, Part I)

Melvin Carter, a PHS officer whom we have met in other connections in this book, was intimately associated with the offsite surveillance program and has supplied this author with much information. The PHS Operations at NTS were headed by Oliver Placak, another well-known and respected PHS officer. In recent years, Carter has reviewed the subject. Of particular interest is a paper he prepared for a symposium "Fifty Years of Radiation Protection" held at French Lick, Indiana, and published in a historical anthology edited by Kathren and Ziemer (Carter 1980). In addition to relating some details of the various programs, Carter emphasized the fact that many of the offsite monitors lived in the more vulnerable communities of Nevada and Utah, partook of the same life as the permanent residents, ate the same food, their children played in the same dust and, incidentally, were exposed to the same fallout.

Emphasis was placed, in both onsite and offsite surveillance, on measuring the gamma dose, and to a lesser extent the external beta dose or the combined dose. It was only by the analysis of air, milk, vegetation, animals, water, etc., that information became available for making some guesses about internal doses independent of calculations from the soil or air content. As the program developed, and especially as public concerns grew, the monitoring function was expanded by a Medical Liaison Officer Network comprising physicians in many states as well as PHS (and later EPA) personnel. Even some epidemiology was begun.

Aircraft were also used for monitoring. The military flew aircraft into the cloud from a detonation to gather samples for diagnostics on the weapons. The same or similar aircraft were used to sample distributed atmospheric radioactivity and to detect, by low-altitude passes over the terrain, deposited fallout.

A brief survey of the PHS environmental radiation surveillance activities is contained in a pamphlet prepared by the PHS (PHS 1964) and NTS; country-wide data are shown in the monthly issues of *Radiological Health Data*,

published by the Bureau of Radiological Health of the PHS. Wrenn (1981a) presented a review of external radiation dose estimates offsite in Nevada and Utah at the annual meeting of the National Council on Radiation Protection and Measurements (NCRP) in April 1980. This is best discussed in the context of internal dose estimates in later sections.

The surveillance, both ground and air, permitted a fallout contour map to be drawn for almost every shot at NTS. Through the kindness of Dr. Gordon Facer, Division of Military Applications, DOE, this author has been provided with a complete set of these maps. There is no question that gaps exist in the contours, particularly for the more rugged terrain, and there is not much information beyond relatively early times postshot. Yet, in view of the cumbersomeness of the early equipment, its limitations in sensitivity, and the fact that shots sometimes occurred daily, the amount of information set down is impressive. These maps have been of great use in some of the reconstruction activities now under way.

Unfortunately, the primary data given in the early days were the external gamma and/or beta-gamma dose rate. How well these do or do not correlate with eventual internal doses is still controversial and at the heart of many current concerns.

B. Early Experiences with Fallout at NTS

The NTS was pressed into service very quickly after the decision was made to have a continental proving ground. The decision to use it was approved by President Truman in December 1950. The first series, Operation Ranger, began on January 27, 1951, and there were four shots between then and February 6, 1951! Worry about fallout at distant cities had little chance under such pressures. There was no advance public announcement. Even people inside of AEC did not know testing was scheduled for Nevada. The lessons that might have been drawn from Julian Webb's deductions and the experience at Trinity were not heeded because those who could have brought them to bear were not involved or even informed. We can see the sequence by a short quote from the 1976 speech by Merrill Eisenbud, New York Operations Office, already cited:

Our first notice of it, apart from the fact that people were reporting booms down in Las Vegas, was when we got a call from Harry Blair, Project Director at the University of Rochester, who had just had a call from Eastman Kodak which said that the snow (it was snowing that day) was radioactive. The University of Rochester had checked the snow and found it to be radioactive, and Harry wanted to know what to do.

I needed a few microseconds to think it over then I called somebody whose name I won't mention and said, "It's snowing up in Rochester and all through the northeast, and I hear the snow is radioactive. What do you know about it?" We knew nothing about bomb phenomenology or where the stuff went or what it contained; fission products were still pretty classified stuff, and none of us even had a working knowledge of what the fission products mixture was like.

My contact at Nevada Test Site said, "You're crazy, Merrill. I was out to Ground Zero, and there's no radiation out there, and you're trying to tell me it's up in Rochester."

And that made me mad, because we had a very serious problem on our hands in that Kodak had already once been affected by radioactive fallout and now they were probably being affected again. So, John Harley and I put our heads together and took advantage of the fact that it was snowing and we called Rochester back

and called people we knew in Cleveland, St. Louis, Buffalo, Boston, and sent teams out from New York as well, and we gathered snow in quart jars. That was a Friday afternoon. By Sunday the people came back with the snow samples; and we lined everybody up with hot plates, boiled the stuff down, and put it into a form in which it could be counted; and by Monday morning we had a map of fallout in the northeast United States, which has never been published. I don't know where the map is; I asked John Harley if he knew, and he thought it was in Washington someplace. But that was the extent of the preparations for those early tests.

Our group was then invited into the preparations for subsequent tests. And we were concerned and assigned the actual responsibility for monitoring beyond the Test Site. The question was: "How far to monitor?", and, "How to monitor?" (Eisenbud 1976, pp. 4-5)

"History" can vary according to the time and place of the beholder. Dr. Howard Andrews, the PHS officer we have already met via an interview and will again in chapter 18, was associated with the Test Managers' Advisory Panel. He was in Nevada at the time of the test in question and recalls that the telephone calls were in the sequence: H. A. Blair, Test Manager and Test Director, Weather Division, Advisory Panel (Andrews 1985). While the results were the same, the details seem to have different versions. The result was a much more careful scrutiny of weather forecasts country-wide rather than for NTS alone and the neighboring states. There was special emphasis on the northeastern quadrant.

These problems led to the development of one of the most used methods for measuring fallout around NTS, nationwide, and, before long, worldwide—a sticky paper that would retain its adhesiveness even when wet and could be spread out on trays about three feet above ground. The sticky paper could be gathered, folded into an envelope, and mailed to the New York Operations Office (later Health and Safety Laboratory) for analysis.

A picture of an early model of the sticky paper tray is shown in figure 12.12A, while one showing Dr. Eisenbud standing among an array of such trays is shown in figure 12.12B.

There was much more than this to the fallout surveillance network. Even at the time of the 1955 Congressional hearings, there was an extensive electronic and sticky-paper network with about ninety stations distributed throughout the United States. The sticky-paper technique remained in operation for many years, partly because of its simplicity and partly because the samples could be measured with laboratory instruments of greater sensitivity and ability to resolve the fallout into components than any field instruments of the day that could be left out in the weather. By 1955, the AEC laboratory in New York had assayed over two hundred thousand samples from the gummed films.

Incidents of high activities in snow or rain at points distant from NTS continued to multiply. These included Troy, New York, with an incidence of rain-out in a violent thunderstorm that will figure in later discussions; Chicago; Rochester (again); Salt Lake City (twice); and many smaller communities. Also, communities closer to the site began to report fallout *without* the intermediation of precipitation.

All of these were measured as external radiation dose rates. None of them presaged significant biological effects in the short term. Yet, the possibility of cumulative exposures through internal deposition and possible contamination of the food chain led to ever increasing concern and controversy. We will consider these presently.

FIGURE 12.12A. (Right) A latex-covered plastic film, 1-ft square on a stand 3 ft above the ground, collects falling dust, which adheres to the latex and is not removed by wind, rain, heat, or cold. Every twenty-four hours the film is changed; the exposed square is folded on itself, sealing adhesive portions together, and mailed to the AEC's Health and Safety Laboratory in New York for measurement. (Courtesy U.S. Congress 1955.)

FIGURE 12.12B. (Left) Dr. Eisenbud with an array of pans for catching fallout. The covers are latex-covered plastic film as described in figure 12.12A. (Courtesy of Eisenbud 1976.)

Just for the record, let it be noted that the rainout in Troy gave maximum readings of beta and gamma radiation of 120 mr/hr at 1 cm above the ground 2.1 days after arrival on the campus of Rensselaer Polytechnic Institute. Most of the readings were lower (Clark 1954). It was possible to make quite clear autoradiographs of the fission products adhering to an asphalt shingle and to a burdock leaf. Decay rates were between -1.26 and -1.52 as power functions of time. Also, the radioactive snows at Ann Arbor, Michigan (Meinke 1951), were carefully analyzed, and the radionuclides present were identified.

It appears that some of these contaminating events reflected the requirement by the military that studies of weapons effects be made at or just beneath the surface, as in the Buster-Jangle series (Hacker undated).

An important feature of the early test shots was the determination of fallout dynamics. This is an aspect of the research around nearly all weapons tests, but it was in the early Nevada tests that some of the most definitive measurements

could be made. Many of the shots were small enough to allow measurements over an area of manageable size, and there was considerable variety in the altitudes, methods of firing (balloon, air drop, high tower, low tower, surface, sub-surface), and differences in the devices themselves.

Much work was done on particle-size analyses and the effect of chemical composition. It soon became apparent that the distribution of fission products was not uniform over the particle-size range, that the radioactivity was frequently attached to larger nonradioactive particles,^(a) that fractionation of activity could take place in a fallout cloud, and that fallout at distant points might be quite different quantitatively from close-in, because of the different retention times of different particle-size distributions in the atmosphere. Furthermore, just as the work in the Pacific brought to light unknown currents in the ocean, the NTS work (along with the air work possible in the Pacific) revealed much about atmospheric mixing, stratification, etc. Indeed, it is said that Lester Machta confirmed the existence of the jet stream from measuring behavior of fallout in the atmosphere.

An early report from UCLA on Operation Jangle (Larson et al. 1952) showed that the average decay rate of fallout material for a surface detonation was significantly longer than from an underground detonation. In 1953, the characteristics of airborne radioactive materials from three of the Snapper shots were described. This work utilized high-volume air samplers for gross measurements and cascade impactors for particle-size analysis (Olafson et al. 1953).^(b)

Mean particle size for the longer-term airborne particles was less than $1\ \mu$, with 95% of the material smaller than $5\ \mu$. Decay rates were different for material from different shots. This particular material was only slightly soluble in water or dilute acid, and specific activity varied inversely with the radius of the particles. These findings indicate strongly that biological effects from fallout entering the body (i.e., as an internal emitter) could not be predicted reliably from measurements of external gamma or beta-gamma dose rates.

In 1954, a study of fallout phenomenology from Operation Upshot-Knothole allowed a discussion of surveys from 1951 to July 1953 (Lindberg et al. 1954). Among the findings was that in areas repeatedly contaminated over a two-year period, 90% of the residual activity was in the first inch of soil.

With particle sizes partly in the respirable range ($10\ \mu$ and below, see chapter 9), there was interest in whether or not inhalation of fallout either directly or via airborne dust could constitute a serious biological hazard. The UCLA group approached this possibility by an analysis of fallout materials from field operations and controlled inhalation studies in the laboratory (Taplin, Meredith, and Kade 1955). They used micropulverized fused insoluble materials from Area T-3 of NTS and also exposed animals (rabbits) to fallout materials by inhalation at stations located along two arcs, 7 and 106 mi from ground zero. They collected urine and tissue specimens and found that little or no radioactivity had entered by the inhalation route.

(a) The NRDL had already pointed this out for samples of fallout from Pacific tests.

(b) While this was a UCLA report, R. H. Wilson from Rochester and F. Lowman from the University of Washington are listed as collaborators. There was much interchange of laboratory personnel in NTS work of the 1950s, particularly to bring in specialists like Wilson on air sampling.

An important summary statement came in a UCLA report by Larson, Neel, and associates (1960). The abstract of this document is reproduced below:

Included in this report are summary statements of significant findings related to the distribution, characteristics, and biological availability of fallout debris originating from testing programs at the Nevada Test Site during the past decade.

The delineation of fallout patterns has been accomplished by the use of aerial and ground monitoring surveys. Only about 25 per cent of the total amount of fission products produced by tower-supported detonations was deposited within distances corresponding to fallout time of $H + 12$ hrs; very much less was deposited by balloon-supported detonations. Fallout particles less than 44 microns in diameter are presumed to be of greatest biological significance. About 30 per cent of the fallout radioactivity from tower-supported detonations was contained in the 0 to 44 micron particles as compared to almost 70 per cent for balloon-supported detonations. Fallout debris from balloon-supported detonations was also much more water and acid soluble than was the debris from tower-supported detonations. The <44 micron fallout particles contained a higher percentage of Sr89, -90 and Ru103, -106 than did larger sized particles, and there was a higher percentage of these radioelements in the particles from balloon-supported detonations. Within distances corresponding to $H + 12$ hours fallout time, balloon-supported detonations deposited a maximum of 0.13 per cent of the theoretical total Sr89 produced; tower-supported detonations deposited a maximum of 2 per cent. Tower-supported detonations also deposited a maximum of 7.2 per cent of the theoretical total amount of Sr90 produced. Beta decay curves approximated the $T^{-1.2}$ decay expression from $H + 12$ to $H + 6000$ hours; gamma decay curves deviated to the extent that irradiation doses calculated by the observed decay values were 1.5 to 2 times greater than those calculated by the $T^{-1.2}$ relationship.

Fallout radioactivity is apparently confined to the first 2 inches of the soil surface unless the surface had been mechanically disturbed. Most of the fallout debris that was redistributed by various environmental factors after original deposition consisted of particles less than 44 microns in diameter; the particles in this size range also represented the predominant contamination on plant foliage. Sr90 levels in surface soil ranged from 31.9 to 142 mc/sq. mile in virgin areas near known fallout pattern midlines and from 7.5 to 22.7 mc/sq. mile in agricultural areas which did not necessarily coincide with fallout pattern midlines. The accumulation of radioiodine by native animals was observed to be a function of distance from Ground Zero. Radiobarium-140, Y-91, Sr89 and Sr90 were major bone contaminants. Post-series sampling of native animals indicated that the accumulation of Sr89 was also a function of distance from the point of detonation; however, the Sr90 accumulation by animals correlated poorly with the strontium unit levels in soils. The strontium unit levels increased in milk immediately following contamination of the farm with fallout debris, and then decreased with time as well as the amount of Sr associated with the cattle's diet.

Observations during the past decade indicate that less than 10 per cent of the total Sr produced from nuclear detonations at Nevada Test Site has been deposited within 200 miles from the point of detonation.

The alleged discontinuity in behavior of particles larger or smaller than 44 μ has become something of a generalization for all of the NTS studies. It has obvious implications for biological availability.

For further particle-size considerations, we turn to a report to the Test Director of Operation Teapot for the Civil Effects Test Group (Barmash et al. 1958). A study was made of particle sizes as a function of distance from ground zero. Obviously, much of the material in the initial cloud is relatively large and drops out soon. For example, this work found that particles larger than 100 μ were present but decreased rapidly with distance from ground zero. By contrast,

smaller particles do not necessarily decrease; they may even increase with distance out as far as two hundred miles. Furthermore, the smaller-sized material tended to be more soluble.

A compact summary-type statement regarding the UCLA work was presented by Larson at the First National Radioecology Symposium (chapter 11) held in 1961 and published in 1963. Larson (1963) gives a review first of the Trinity site resurveys, followed by a summary of the characteristics and measurements of fallout from NTS operations. He underscores the importance of knowing as much as possible of what goes on in the first few minutes after a detonation to understand and predict subsequent behavior of the fallout and its potential for biological effects. He reviews the particle-size information and radiochemical findings for several types of shots and gives the kiloton yields in each. Also, he gives estimates of the total curies of ^{89}Sr produced (27,350,000), deposited at $H + 12$ hours (285,300) and available for deposition elsewhere (27,064,700). For ^{90}Sr , the comparable figures are 162,485; 8,066; and 154,419. Solubility in water and 0.1 normal HCl was considerably greater for the balloon than for the tower shots.

UCLA was not the only laboratory involved in this work, of course. The military had extensive cloud sampling and air sampling activities, as did Sandia Laboratories, Los Alamos, and Livermore. However, these were more oriented toward weapons behavior and of less pertinence to biomedical evaluations.

The U.S. Weather Bureau played an important role. Useful summaries appear in the Congressional hearings. One report that gives a clear idea of just how the information was gathered concerns the North American fallout from Operation Teapot (List 1956). This work involved collaboration with the Radiological Physics Division at Argonne National Laboratory and elsewhere. The work is full of fallout distribution maps, autoradiographs of rain collection, and details of the gummed film network.

The New York Operations Office of AEC prepared a general and historically oriented dissertation emphasizing data from the tests of spring 1952. They compared airborne with settled dust and emphasized that the magnitude of the depositions was minute, especially when compared to the natural radioactivity of the earth's surface and atmosphere (Eisenbud and Harley 1953). Only close-in "hot spots" had levels of real biological concern at the time.

An addition to the methodology was described by Romney et al. at UCLA (1959). This was a granular collector with a removable mylar plastic liner in a tray filled with polyethylene plastic granules $1/8$ to $3/16$ in. in diameter. It was used extensively in the 1957 series (Operation Plumbbob). Its particular advantage was ease of separation of primary fallout particles for physical and chemical characterization.

What does all of this have to do with biology and medicine? Why should the AEC Division of Biology and Medicine and the PHS expend resources and personnel on measuring and characterizing fallout? Obviously, the first job is to find where it went and seek out any areas of potential danger to humans and to the environmental fauna and flora. The second job is to understand enough about the relationships involved to be able to correlate something readily measured (external beta-gamma or gamma dose rates) to effects from the fallout on body surfaces and after internal deposition. Third, the persistence and characteristics over time are essential to know if long-term possible doses and effects are to be predicted. We will examine some of the first returns in biology in the next section.

C. The Early Biological Information from NTS

The UCLA people produced the bulk of the onsite and near offsite biological information in the early years. In a report on Operation Upshot-Knothole, Lindberg et al. (1954) describe radioecological surveys that had been in progress intermittently from September 1951 through July 1953. Samples of native soils, plants, and animals before, during, and after the test series over distances out to 30 mi from ground zero suggest that microcurie-levels of radionuclides (not specified) are available for absorption and metabolism by grazing animals. They found amounts in femurs and livers of jack rabbits threefold higher than in 1951, while the amounts associated with plant materials were increased by a factor of two. Ingestion, rather than inhalation, is given as the primary intake route. In a comparable report by Lindberg et al. (1959) concerning Operation Teapot in 1955, the role of particle size in plant contamination (the 44- μ phenomenon) is fully described, along with the solubility of the material on plant foliage (only 6% to 21% in 0.1 N HCl). Tissue burdens in animals decreased with distance from ground zero much the same as the plant contamination. Interestingly, the beta activity in rabbit femurs tended to remain fairly constant to as far out as 140 mi.

Amounts of iodine in thyroid are first mentioned in this report. The thyroid burden at 60 mi from ground zero was higher than at either 10 or 140 mi. They attributed the thyroid activity to ^{131}I .

Importantly, the gross tissue burdens in animals were more or less proportional to the contents of the gastrointestinal tract, suggesting again that ingestion rather than inhalation accounted for the tissue contents.^(a)

Because plants are selective collectors for the small particles, and the small particle concentrations in the fallout remain more or less constant with distance for many miles, the amount of bomb debris in grazing animals tended to be independent also of total fallout. Details for other similar surveys can be found in the annual reports and in more compact and available form in the monumental summary prepared by Larson et al., Director of Program 37 of Operation Plumbbob (Larson et al. 1966). While this test series took place in 1957, it required several years to measure all of the samples in the laboratory, get the report declassified, and correlate with earlier years. The report reiterates the facts already quite evident, viz., chronic tissue burdens in animals do not correlate well with measured external dose rates of environmental contamination, nor does the activity associated with plant materials. Assimilation of specific fission products by animals is highly variable. In addition to the finding on radioiodine mentioned above, the body burden of radiostrontium in desert rodents six months following the fallout event was about five times greater at 130 mi than at six other locations ranging from 40 to 400 mi from ground zero. This was for Operation Teapot. For Operation Upshot-Knothole, the body burdens in native rodents at 130 mi were seven times higher than on the test site. Furthermore, the ratio of ^{89}Sr and ^{90}Sr was variable, which suggests some fractionation phenomena even for these closely related isotopes, based perhaps on particle-size phenomena.^(b)

(a) Undoubtedly, this reasoning underlay the conclusion in the earlier report also.

(b) Remember there are differences in the chain from ^{89}Kr to ^{89}Sr versus ^{90}Kr to ^{90}Sr that could result in attachment to different particle distributions.

Despite the apparent complexities described above, a broad view of the biological availability showed reasonably consistent patterns. Note the following from the summary of chapter 7 from the Operation Plumbbob report:

1. The data presented are representative of the relative fission product accumulations in adult animal population of the species studied within an overall factor of two.
 2. Comparison of the biotic data from five different detonations shows a marked similarity in the pattern of mixed fission product accumulation (total beta activity) in animal tissues. The similarity is apparent when the data are related to the time at which fallout occurred. Total activity in tissues tended to decrease as the fallout time-of-arrival increased.
 3. The rate at which the total beta activity in tissues decreased with increasing time of fallout was slightly greater for the balloon supported Shot Priscilla than for four tower supported detonations and correlated with differences in the amount of the less than 44 micron fallout material that was deposited.
 4. For comparable locations within the two fallout patterns (Priscilla and Smoky), the amount and kinds of radionuclides present in bone samples were similar despite differences of orders of magnitude in the amount of fallout deposited by the two shots. This similarity can be accounted for by the relatively higher solubility of the Priscilla fallout material.
 5. Biological "hot spots" were identified with Boltzmann (78 miles from ground zero), Diablo (60 miles from ground zero), and Shasta (172 miles from ground zero) fallout patterns. The degree of biological accumulation in the Boltzmann and Diablo hot spots reflected the heavy deposition of fallout, particularly of the less than 44 micron fraction, in these areas. However, high values occurred in animal tissues sampled from a Shasta location even though dose rates obtained by ground and air monitoring failed to reveal correspondingly high levels of deposited radioactive debris in that area. Other animal tissues sampled from the Shasta radiological hot spot did not show high fission product concentrations.
 6. Apart from the exceptions shown by comparison of the tower-supported Shot Smoky and balloon-supported Shot Priscilla, the pattern of biological accumulation of beta activity appears to be similar for the detonations studied during the Plumbbob, Teapot, and Upshot/Knothole Test Series.
 7. Jackrabbit bone levels of Sr^{90} from animals in Station VI Area were about the same in 1958 as in 1957. There was an increase reflected in 1959, followed by a decrease to the 1957-58 levels in 1960, and an abrupt drop in 1961, i.e., from 25 to 10 pc $\text{Sr}^{90}/\text{gm Ca}$. This occurred despite the apparent constant level of Sr^{90} in soil.
 8. Data suggest that the higher levels of Sr^{90} in the indigenous animals are associated with animals which were living in the early sequence of contamination, i.e., during and immediately after fallout, rather than with animals that were born later and merely lived in the contaminated environment.
- (Larson et al. 1966)

The chapter is full of tables and graphs and potential correlations. However, the variability of the observations, which the authors note, is such that only broad trends can be considered along with some interesting sidelights. For example, there is less ^{90}Sr in the bones of kangaroo rats than in jack rabbits, probably because of differences in living habits. All of the levels recorded, given in picocuries or strontium units (pCi/g Ca, see section on global fallout), are far too low to presage any eventual biological effects. This work is thus pertinent largely to the question of biological availability.

A detailed published work on ^{90}Sr in the kangaroo rat and jack rabbit shows several points of interest (Neel and Larson 1963). The relation between soil concentration and strontium in bone was investigated in animals of Area I, a

relatively close-in area 13 mi from the NTS center. Operation Buster-Jangle raised soil levels of ^{90}Sr in this area by approximately a factor of ten, and a subsequent shot added more. The bone content rose to 33 strontium units (section VI B) by fall 1952. Despite additions from other shots that brought the soil concentrations to double or more, the bone content decreased with time. It went up by a factor of two during the Plumbbob series, even though the average measured soil content remained essentially constant. Only after the Kiwi shot in 1959 (see chapter 14) did the bone levels reach above those seen in 1951. They went back down in 1960 and further down in 1961. The movement of fallout isotopes, even in a desert ecosystem, clearly is not simple.

It happens that Neel and Larson got many samples close to the Smoky tower shot in 1958, as well as some as far out as 432 mi. Since this shot has assumed great importance in the recent retrospective analyses, the table from Neel and Larson showing the ^{90}Sr in soil and in jack rabbit bones in 1958 and 1959 is reproduced as table 12.8.

TABLE 12.8. 1958 Strontium-90 Soil Levels and 1958 and 1959 Jack Rabbit Bone Levels at Various Sampling Sites in Nevada and Utah

The most obvious generalization is not to predict body or bone burden except in the most general way directly from fallout measurements. Also, it bespeaks the virtues of having some direct measurements on biological materials in hand—not an easy assignment for contamination of such large areas.

Marvin Van Dilla, who was instrumental in the development of gamma-ray spectral analysis at Los Alamos, brought the technique to bear on analyses of rumen contents and tissues from cattle grazing in the vicinity of NTS (Van Dilla 1959). The purpose was to check on gastrointestinal absorption of the several isotopes (Langham 1960). He found a predominance of cerium, ruthenium, and $^{95}\text{Zr}/^{95}\text{Nb}$ in the food ingested by the animals, while ^{137}Cs was below detection limits. Yet, the liver and muscle showed a prominent ^{137}Cs peak, plus a trace of $^{95}\text{Zr}/^{95}\text{Nb}$. Cerium and ruthenium were below the limit of detection in the tissues, even though they predominated in the rumen. Thus, many of the radionuclides present from fallout in the environment must be quite insoluble and poorly absorbed. Their presence alone in the environment or even in the food does not necessarily gauge hazard on ingestion. Some of the data are shown in table 12.9.

TABLE 12.9. Radionuclides in Cattle Grazing in the Vicinity of the Nevada Test Site (1958-1959)

Sample ^a	$\mu\text{mc/kg}$

An indication of some of the more complex and experimental, rather than purely observational studies in connection with the Nevada tests, is seen in some work done in Project 2.7 of Operation Jangle. Smith, Boddy, and Goldman (1952) went to NTS from the NIH to conduct two biological experiments, one for a surface test and one for an underground detonation. The primary purpose was to assess the hazard due to inhalation of dust and to compare the external and internal doses in exposed test animals. These were placed at 2,500; 5,000; and 8,000 ft from ground zero on arcs. Animals were sacrificed at H + 10 to H + 24 hr, at D + 2, + 4, + 9, and + 70 days. Homogenates of lung, liver, spleen, kidney, blood, bone, urine, and gut contents were dry ashed for measurement of radioactivity, and samples of soft tissue were prepared for autoradiography. The NIH workers measured external dose with National Bureau of Standards (NBS) film dosimeters both at the surface and in foxholes in which some of the animals were placed. The internal doses were determined by calculation from

the tissue contents. The external gamma doses from the surface test were less than 10 r^(a) at all positions on the 5,000- and 8,000-ft arcs. The doses along the 2,500-ft arc ranged from 265 to 300 r. External gamma doses from the underground test were considerably higher.

As a function of organ and time, radioactivity in tissues from all animals exposed during the surface shot ranged quite low, from 0.06 to 2.13 μ Ci, while those from the underground test ranged from 2.22 to 31.1 μ Ci. Integrated doses to the lungs given in rep^(b) were from 0.19 to 8.83 rep. The radioactivities fell off rapidly with time and were below the limits of detection by D + 9. The conclusion was that internal contamination from inhalation and/or ingestion was not significant compared to the external doses received under the conditions of Operation Jangle.

This conclusion is for the short term. The autoradiographs of lung tissue showed three distinct types of radioactive particles: a pure alpha emitter, probably ^{239}Pu ; a particle with mixed alpha and beta radiations; and one emitting only beta particles. Since the experiment was short-term, no information was gathered regarding long-term doses or possible effects. However, a significant lifetime dose could be envisaged from particles like the plutonium in the lungs, if it were relatively insoluble and became fixed.

A further study of lung dose came from the New York Operations Office (Blatz and Solon 1953). This was a calculation of potential lung dose to humans from measurements made on radioactive airborne dust collected near ground level at about 275 mi from NTS in fall 1951. Using the specific activity at the point of collection as a function of time after the explosion (not identified), an integral dose to infinity of about 17 mrep was calculated, an inconsequential dose physiologically.

Taplin, Meredith, and Kade (1955) evaluated the possible inhalation hazard by analysis of results from field operations and parallel controlled inhalation studies in the laboratory. This work came from UCLA.

Detection and quantitation of fallout particles in lung, based on a lung excised from a diabetic in March 1963, came from work at the University of Michigan School of Public Health (Wegst, Pelletier, and Whipple 1964). They were interested in finding and identifying single particles. They found four in the removed lung (right), but total activity in areas of the lung in which particles were not identified was not greatly different. Thus, only a portion of the lung activity came from identifiable particles. (They analyzed for ^{141}Ce , ^{144}Ce + ^{144}Pr ; ^{103}Ru , ^{105}Ru + ^{106}Ru ; ^{95}Zr + ^{95}Nb ; and ^{40}K .) Doses were negligibly small.

One of the few truly ecological studies of this early period concentrated on Frenchman's Flat and Jackass Flats, where the majority of the tests occurred (Allred and Beck, 1963). Since there was no satisfactory investigation of the flora and fauna of the area before the tests, the study has many problems. The NTS appears to be on the border between the Great Basin and the Mohave Desert ecosystems and, therefore, only small changes in locale make enough difference that simple comparison to adjacent areas could not serve as an adequate control. The findings are summarized by the following:

(a) This work was done when the abbreviation for roentgen was r rather than R. We use the terminology used by the investigators.

(b) Roentgen equivalent physical, an early term that can be equated roughly to the rad for present purposes (see chapter 16).

1. There is a relatively rich fauna despite appearances to the contrary.
2. Destruction of plant communities was quite evident.
3. Insects and other invertebrates showed more species inside the disturbed areas than outside, while mammals did not show this effect, except that their ranges seemed to have been extended. (Transient increases in certain groups in a disturbed area seem to be moderately well known.)
4. More work is needed simply to classify the forms found, particularly the invertebrates, since many unidentified species were found.

These examples give the flavor of those early biological programs conducted at NTS that have a bearing on the role of radioactive materials deposited in the body. Much that concerned only external dose has been omitted, especially the large programs looking for the effects of neutrons and neutrons with gammas. In comparison with some of the extensive plans that involved much more genetic work and very large numbers of animals, the amount of such work seems rather sparse. However, much was being done or about to be done concerning offsite exposures at from moderate to considerable distances and on the contamination of food supplies. This will concern us in the following sections.

D. Offsite Exposures Near NTS

In this section, we will use the term "offsite" to connote exposures within a few hundred to a thousand miles of NTS and exposures linked to specific events at the site. We are not including here continental fallout or global fallout, even though the source of these may have been in part operations at NTS. These are better discussed as separate entities (section VI).

1. People—Phase I

a. The Background

It is obvious from what was presented in sections B and C of this part that the presence of fallout measured either at the time or retrospectively by analysis of soils or of plants and animals could be demonstrated several hundred miles from NTS.^(a) We have said nothing yet about possible involvement of human communities in these events, and it is time we did.

The prevailing winds at NTS are out of the southwest with frequent shifts to south or west and occasional vectors from north quadrants. As a result, the fallout clouds moved mostly north and northeast from the site, occasionally east, or on rare occasions, southeast or south. The most involved communities were to the north and northeast of NTS in Nevada and Utah, but Idaho and Montana were also favored on occasion. Saint George and the rest of Washington County in Utah; Salt Lake City and surrounding communities; and various communities, mostly small, in Nevada have been featured most frequently in the investigations. Some typical trajectories of fallout from NTS detonations are shown in figure 12.13. These pertain to shots in 1962 but can serve as examples of typical behavior.

(a) In addition to the UCLA, AEC, and PHS work already cited, further details can be found in Dunning (1958, 1959), Klement (1965), and in the Congressional hearings already cited.

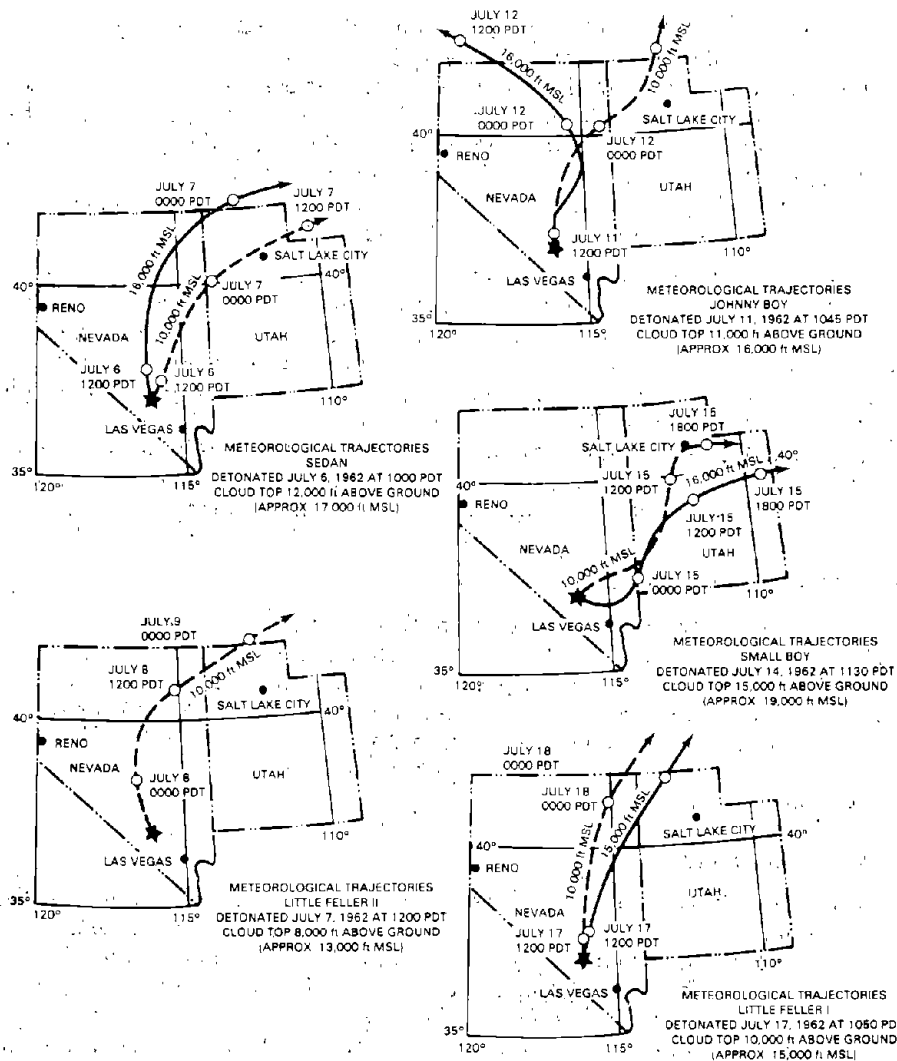

FIGURE 12.13. Typical trajectories of fallout from Nevada Test Site detonations. The line purports to describe the path of the cloud center. There was, of course, some lateral spread, particularly as time passed. (Redrawn from Mächta 1963. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1963.)

The evaluation of dose and thus of hazard depended in the early 1950s primarily upon the film badge, other measurements of the external gamma or beta-gamma radiation doses, and of gross radioactivity measured in air and in water. These were found to be well within limits set by AEC and later by the Federal Radiation Council (FRC) for population exposures. Details, voluminous

for external gamma radiation, are given for the early to mid-1950s by Dunning (1958).^(a) Following the dictum that if the external dose was below limits the dose from deposited radionuclides would be negligible and the finding of very low quantities in water, both the exposed population and the monitoring teams mostly decided that all was well (or, at least, not bad). Remember that gamma spectrometry only came into its own about 1958, and, before that, identification of individual radionuclides required laborious radiochemical procedures not at all applicable to field determinations. Iodine became the cause célèbre.^(b) As Eisenbud and Wrenn (1963, p. 1134) remarked in connection with the measurement of iodine, "neither the proper tools for measurements nor the prerequisite interest existed" for the prior tests.

The results of the experimental laboratory work with animals described in earlier chapters showed more and more clearly that even low levels of exposure to certain radionuclides might have very real biological effects, and the fever of activity grew for the measuring of specific isotopes in all fallout. The presence of the three-year moratorium on testing made it possible to go back around the test site and analyze for the deposited fallout at leisure and in more depth, especially to look for cesium and strontium, which had reasonably long half-lives. The results indicated a few instances of high cesium concentrations and a few instances where the strontium concentrations might have originally approached undesirable levels.

It was the participation of the food chain and particularly the iodine-foilage-cow-milk-human sequence that led finally to serious concerns in and about the communities treated to large and successive doses of fallout from NTS. The trigger was measurements of iodine isotopes in the fallout, on foliage, in water and food, and in the thyroid gland of humans and animals from tests occurring after the moratorium had been lifted. (Unfortunately, none of the iodine from the earlier tests was left to measure, so cumulative doses could only be guessed at.) We will review the iodine story as representative of the approaches taken. Measurements of fallout iodine in thyroids started, of course, well before this time. Remember Windscale (chapter 11)? Van Middlesworth (1956), formerly of Berkeley and then at the University of Tennessee in Memphis, was probably the first to report iodine from continental and global fallout in cattle and sheep of the United States. Also, White and Jones from Berkeley (1956) showed uptake of ^{131}I by human and bovine thyroids (151 human and 1,000 beef thyroids) gathered in northern California and assayed between October 1955 and October 1956. The thyroid burden of ^{131}I in the humans was much lower than in the cattle. (More in section VI.)

b. University of Utah and Utah State Work

As for Windscale and the Pacific Proving Ground, it was the thyroid of the child that appeared most vulnerable because of its small size and rapid uptake of radioiodine. By July 1962, the sampling of fallout had become more sophisticated locally as well as nationwide. It happened that the University of Utah

(a) This summarizes extensive offsite monitoring activities by the PHS group under Oliver Placak and UCLA data collected by Kermit Larson, augmented by work from H-Division of Los Alamos and the AEC Health and Safety Laboratory in New York.

(b) Yes, iodine again, just as at Windscale and at the Pacific Proving Grounds!

people were engaged in a statewide radiological ecology study in cooperation with the Utah State Health Department. On July 7, 1962, Pendleton was in the field about twenty miles from Salt Lake City with a group of students measuring background radiation. A dusty cloud was observed, and when it arrived the radiation levels went to one hundred times normal background (i.e., to 2 mr/hr) (Pendleton et al. 1963). The State Health Department measurements on the next day showed gross airborne beta activity of 900 pCi/m³. This galvanized a very active collection of milk samples^(a) and analysis, especially for ¹³¹I. Thirty-nine dairy farms around Salt Lake City were sampled, and external counting of thyroids in humans on these same farms was initiated in August.^(b)

The ¹³¹I content of these milk samples varied from 0 to 800,000 pCi/l. This variation was due partly to location (these fallout clouds could be quite limited in extent) but was due mostly to feeding practices at the time. The maxima were in the milk obtained from cows feeding on fresh green forage or in wet meadows. The minima were in those cows that happened to be on stored feed at the time.

There were a total of seventy-six stations, and the ¹³¹I intake of persons drinking one liter of milk per day from a given station was calculated. The thyroid and total body counting work gave similar wide variations. The dairy families counted in August showed the amounts in thyroid given in table 12.10.

The radiation doses associated with these amounts were calculated by Pendleton et al. (1963), but only one was given officially. This was for the peak uptake of 800,000 pCi. The associated dose was 14 rad assuming an uptake of 30% by the thyroid, an effective retention time of 7.6 days and a thyroid weight of 2 g.^(c) This was, of course, an infant.

The possible thyroid doses were expanded upon a bit by Pendleton, Lloyd, and Mays (1963) in a paper published in *Science*. A thyroid dose of 1 rad would be expected for infants averaging 58,000 pCi; the adult dose would be about one-tenth that of the infant dose under the same conditions.

These doses are, of course, not in the same class with those to the Marshallese (section III D 2) or probably those from the Windscale event. Yet, the maximum of 14 rad was well above the 0.5 rad of the RPG. Even the average infant dose of 1 rad was twice the Guide. The chief cause for concern was the fact that about 53,000 Utah children may have been exposed to the 1962 releases. How many? We will have to return to that question.

Pendleton et al. (1963) attempted to get some sort of cumulative dose estimation over the period of the Nevada tests. Since there were no data for milk in the area of concern prior to 1962, and none for iodine in soils, they fell back on

(a) A milk collection network was, of course, already in operation for global fallout (see section VI).

(b) It was thought that the incident described represented fallout from the Sedan shot on July 6. Others came in rapid succession, however, up to July 17 so that thyroid iodine content could not be ascribed to any single event. Furthermore, as Mays described in the 1963 Congressional hearings at which the same biomedical data were presented, the beta activity from the Sedan shot was not from fission products but from tungsten activated by neutrons. However, there were many other events that might have contributed ample ¹³¹I. There was no question that the peak in activity was ¹³¹I.

(c) In later Congressional hearings on this same work, Mays (1963) gave an average infant dose of 1 rad.

TABLE 12.10. I^{131} in Utah Dairy Families Measured by Thyroid Counting and Total Body Counting

Person	Sex	Age	I. Milk/Day	Day Counted	pc I^{131}	Per Cent Uptake*

an estimate based on the gross beta-particle measurements made in air (Dunning 1958 and the Utah State Department of Health). With many assumptions and normalization of the air figures to the 1962 data, they came up with the possible doses to thyroid given in table 12.11. These were expanded upon in the Congressional hearings to give estimates calculated from the yield as well as from the air measurements.

TABLE 12.11. Estimated Radioiodine Doses to Thyroids from Fallout in Utah from Several Nevada Tests

Explosion Dates	24-hr Av. Air β Concen.	Est. Av. Infant Thyroid Dose	Number of Exposed Children Under 2 Years	Air Sampler Location
7 May, 1952	20,000 pc/m ³	6 rad.	41,000	Ogden, Utah
19 May, 1953	287,000	84	700	St. George
15 July, 1957	2,900	0.9	47,000	Salt Lake City

July, 1962	3,400	1.0	53,000	Salt Lake City

Source: Modified slightly from Pendleton et al. 1963. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1963.

It was recommended that any farm in the Utah group with milk averaging over 1,000 pCi of ¹³¹I per liter of milk^(a) should put their cows on stored feed and that the milk should be diverted to cheese making, etc. which allows time for radioactive decay.

It appeared that heavier contaminations may have occurred in earlier years, and the average cumulative dose to an infant in 1953 might have been as much as 84 rad (table 12.11). But we must make many assumptions regarding the ¹³¹I content of these clouds. (This one was in St. George, Utah, not Salt Lake City. The pretty town of St. George got more than its share of NTS fallout.) On the basis of such figures and the moderately large population at risk, many people concluded that these exposures warranted a medical survey for thyroid nodularities and other thyroid dysfunctions.

c. The Knapp Study

Harold A. Knapp, a former employee of the AEC (Fallout Studies Branch, Division of Biology and Medicine), but by the time of the 1963 hearings on the staff of the Institute for Defense Analysis in Washington, presented a report calculating ¹³¹I in fresh milk and human thyroids following a single deposition of nuclear-test fallout (Knapp 1963). This document appears to have been prepared specifically for the hearings. It was based on the accumulated data from many sources. It concentrated on the fallout from the Small Boy shot in July 1962 but bore also on the findings of Pritchard, Mays, Lloyd, et al. at the University of Utah, which may have involved other shots as well. The Knapp report includes both calculated and observed levels of radioiodine in thyroids for persons in exposed families in Utah, albeit taken from different sources. It was a detailed analytical discussion with many cross-checks and comparisons of different computational schemes. The conclusions, summarized below, were drawn, we emphasize, from measurements that were not initially intended to investigate the relation between ¹³¹I levels in milk and the external gamma levels from fallout on the ground.

(a) The figure chosen by the FRC (see section VII) for the RPG was 100 pCi/l (bottom of Range III), but this applied to longer-term exposure.

1. Levels in fresh milk reach a maximum in four days and thereafter decrease exponentially with a half-time of five days.
2. The maximum level in fresh milk in μCi (pCi) ^{131}I per liter (I_{max}) showed ratios to the external gamma dose rate at $H+24$ hr measured in mr/r (r_0), ranging from 26,000 to 100,000 (i.e., I_{max}/r_0). If broader assumptions are made, the ratio ranged from 18,000 to 220,000. These are best estimates for a series of communities from fifty to four hundred miles from ground zero.
3. A model was developed for estimating the ^{131}I content of the human thyroid and the radiation dose resulting from daily consumption of fresh milk from cows grazing on a pasture on which there had been a single deposition of fallout.
4. Calculated thyroid burdens in people on dairy farms in northeast Utah based upon measured levels of ^{131}I in milk were compared with in-vivo measurements. The calculated burdens ranged from one to three times the measured burdens, using an assumed consumption of one liter of milk per day. Calculations based on the individual's own estimate of intake did not correlate well at all with measured quantities.
5. On the basis of all this, the thyroid dose due to ^{131}I deposited from a single event was compared with the calculated lifetime whole-body dose due to external gamma radiation from the same fallout. For a one-year-old child, the internal dose to the thyroid could be from 60 to 240 times the external gamma dose, if the calculations were correct.
6. Furthermore, the calculations indicated that milk levels of from 1,000 to 5,000 μCi of ^{131}I per liter could develop when the external gamma levels from the fallout were too low to be distinguished from natural background using ordinary field-survey methods.^(a)

Knapp's report is supported by data from many quarters. Of particular interest are derivations of the kinetics of ^{131}I in milk from the Windscale accident (Booker 1958; Garner 1960) compared to those from the Nevada-Utah field conditions. (They were surprisingly similar considering the large differences in conditions.) The applicability to the shots other than Small Boy is examined, along with the role of particle size, etc. There are a total of eight appendices to the Knapp document.

To go further would be beyond our scope. However, we should pause to state that this report was subject to an exhaustive review by an ad hoc committee of the Joint Committee on Atomic Energy of the U.S. Congress. Members were: Cyril Comar, Cornell; John Gofman, Lawrence Livermore; Wright Langham, Los Alamos (Chairman); Julian Nielsen, Hanford; and Oliver Placak, PHS Southwestern Regional Health Laboratory. The chief problems raised were the uncertainty of the field measurements, and thus of r_0 and the extent to which this variability had been accommodated by the author. The resulting instability of the derived figures, the fact that different sets of data of different origin had to be used for the two prime parameters under discussion, the fact that the only checks on the thyroid activity calculations were measurements

(a) Before we get too excited, let us remember that 5,000 pCi is only 0.005 μCi and that the yearly RPG for the general population (children are the critical group) is 36,500 pCi of ^{131}I or 0.037 μCi . If taken for a year at 5,000 pCi/l , the RPG would clearly be exceeded. However, the duration of intake at such high levels was considerably shorter than one year, of course.

done by different people, and the difficulty of extrapolation to other situations were cited by the committee. Nevertheless, the committee approved publication and distribution of the report primarily to "stimulate interest of the scientific community in the ^{131}I problems." There was a detailed response by Knapp.

d. Other Statements of Concern

There were many other sets of testimony at the 1963 hearings on potential overexposure of populations around NTS. Some of these were similar to the types of problems described above. Others addressed the problems in a more generic manner and included aspects of continental and global fallout.

These statements can be reviewed best by perusal of the 1963 Congressional hearings, which included testimony from committees on radiation information from various states pointing to one or more incidents of high fallout within their borders, comments by E. J. Sternglass that we will save for a separate section, a statement from Eric Reiss at Washington University in St. Louis for the Greater St. Louis Citizens Committee on Nuclear Information, and others.

Separate from the hearings was a report from LLL in 1966 that estimated thyroid doses of 50 or more rad to children in Nevada and Utah during the period 1952-1955 (Tamplin and Fisher 1966) and exceeding 100 rad for children in Washington County, Utah (St. George).

Since these reports and presentations do not involve new research information or measurements, but are primarily reinterpretations or recalculations of data already available, we recommend that the reader consult the cited hearings and the voluminous discussions of the day issued by the numerous organizations.

e. The Baneberry Event

Several years after the work of the 1960s, but still pertinent to what we are calling Phase I of the offsite exposures of people, was what is known as the "Baneberry Event." This was an underground test conducted at NTS on December 18, 1970. Unexpectedly, it vented and produced a cloud of radioactivity that ranged over central and northern Nevada and into Utah. At that time, the Biomedical Division of LLL and the Department of Radiological Health of the University of Utah were conducting cooperative studies of radioecology throughout Utah. As part of this program, designed to document the movement of already deposited radionuclides in the environment, extensive sampling operations were already in progress. The amounts in and depositions from the Baneberry cloud were thus obtained almost adventitiously. They are described with care by Pendleton et al. (1971).^(a)

There were no measurements on humans, but ample analyses were made of air filters, water, vegetation, and animal organs. The last included ^{131}I in thyroid glands of sheep, deer, and rabbits. The measurements, coupled with prediction models, were used to predict human hazard from the Baneberry venting.

(a) "The radiation doses to humans, including infants, from all significant radionuclides known or calculated to have been released in the Baneberry venting were estimated for the Salt Lake City area, where the highest air activities were observed in our sampling network. In each case, the largest potential dose was to the thyroid. The estimated dose received from inhalation and submersion was 0.005 rem to the thyroid. . . . The total dose to a child's thyroid resulting from the cow-milk pathway was calculated to be approximately 0.012 rem based upon measured concentrations of ^{131}I in hay and milk." (Pendleton et al. 1971, p. 168)

It should be noted that exceptionally heavy snowfall was on the ground, and winter feeding practices were in effect at the time of the Banberry venting. This undoubtedly prevented more significant human exposures. Calculations made for summer feeding conditions yielded a thyroid dose to children from age zero to one year of about 1.3 rem for a dry deposition condition and as high as approximately 100 rem if complete deposition of the ^{131}I in the cloud had occurred by virtue of heavy local precipitation.

f. Comment

Whether or not the details are correct or the models accurate for the cases cited, they dispel any possible lingering doubt that internal doses from fallout radionuclides bear only a tenuous relationship to the measured external gamma dose, especially on the ground. If the nuclides enter humans via the food chain, the relationship is essentially nil. This is true whether the radionuclide is strontium, cesium, or iodine. The practice of the early 1950s of relying on external gamma measurements is obviously inadequate, in retrospect.

There are strong implications in much of the testimony that the situation was not appreciated within "the establishment." Yet, there is ample indication in the literature that all parties concerned were coming to appreciate the importance of the new facts, especially about the food chain, at about the same time. (See, for example, the last part of Part 2 of the 1963 hearings.) It might be said that all were learning together as new facts were gathered.

In due course, action was taken on iodine in the form of revising the Code of Federal Regulations. The permissible level for iodine in the environment was reduced by a factor of 700 (Appendix I of Part 10, CFR 20).^(a) Also, if food is involved, restrictions on intake of any radionuclide of a factor of three may be applied (see, for example, Section 20.106e of 10 CFR 20).

There was and still is controversy as to the doses imparted to the various populations by these events. The early concentration on longer-lived nuclides like strontium and cesium has left us in better shape for reconstructing the probable doses from these than from a short-lived radionuclide like ^{131}I . The possibility that only a few members of the population received the higher doses cannot be conclusively refuted. Mays, whose work (cited above) is frequently quoted as indicating a cumulative thyroid dose from ingested ^{131}I of from 5 to 50 rad *for all children*, stated clearly in his second round of testimony (Mays 1963) that the potential 14-rad dose came from milk from one farm out of thirty-nine, and that the average dose for the farms studied was probably 1 rad. There is no question that a farm family drinking milk from their own highly contaminated source would receive high thyroid doses. However, since milk is pooled for the larger population centers and frequently shipped long distances, the average child probably received a different intake, lower than the maxima by a significant factor. On this basis, many took the view that the high doses involved only a few isolated cases (Seaborg 1963).

The dilemma must remain insofar as iodine is concerned. We can never bring back measurements that were not made, nor can we reconstruct the milk-drinking habits of these populations in the early 1950s any better than current information permits. Backward extrapolation on the basis of air concentrations

(a) Strictly speaking, this applied only to the effluents from light-water-cooled reactors. More in chapter 15.

or on the basis of yield from the devices involves assumptions piled upon assumptions and is recognized by all as subject to large errors. Yet, this is all we could or can do.^(a)

Obviously, the next step was to look for long-term biological effects in the exposed populations. We will now examine that work.

2. People—Phase II—Clinical Studies and Epidemiology

The clinical studies were a logical outgrowth of the findings detailed as "Phase I." They were considerably broader than possible thyroid pathology since there was concern also for possible increased incidence of leukemia, even of bone tumors. The work was slow to start. There were many reservations about the scientific feasibility of such studies. The population was not large by epidemiologic standards. There was also concern that mounting clinical studies would engender undue apprehension in the populations involved.^(b)

This author has in his possession a document in draft form dated July 23, 1965, entitled "Leukemia Mortality in Southwestern Utah" by Edward S. Weiss of the PHS. It is marked "Forwarded by Memo, 9-9-65," and attached to it are some formal "comments" on the plan. These comments point out the many problems in the draft report and conclude, "it is difficult to accept the idea that the observed number of cases in Iron and Washington Counties, Utah, 1950-1964, is indeed excessive, especially in the absence of information on the number of cases during the same period in equally small population groups around the country."^(c) It appears that this draft report was never published in the form written.

There was also a protocol for a clinical project to be undertaken by the National Institute of Dental Research and the National Institute of Arthritis and Metabolic Diseases for study of 2,000 residents of Washington County, Utah, and a control area. There was to be a dental study, a thyroid study, and two relatively unrelated adventitious studies. The exact fate of this plan is not clear, but it seems to have at least stimulated further work.

At the time of the 1963 Congressional hearings, both the PHS and the AEC announced plans for a study of thyroid and bone cancer, leukemia, and congenital malformations in Utah and Nevada. It was indicated that this study might serve as a pilot project to determine the feasibility of a national program. Like all studies of this nature, the results were slow in coming, partly because of the irreducible latent period for development of many of the dyscrasias under study. However, the work did get done. The results began to appear in the 1970s. We will begin with the findings concerning the thyroid.

In 1971, Weiss and colleagues from the Bureau of Radiological Health (Weiss et al. 1971) reported on the search for thyroid abnormalities, especially nodules,

- (a) The long-term persistence of ^{90}Sr and ^{137}Cs in soil, vegetation, and small mammals on NTS was confirmed as late as 1980 by Romney et al. (1981).
- (b) As it turned out, this was, like many such apprehensions, incorrect. When the work finally got under way, there was general acceptance, including enthusiasm in the groups who regarded themselves as most highly exposed. Indeed, the reaction seemed to be more along the lines of "It's about time."
- (c) It appears that the culprit was taken as the external gamma dose, and thus this work may not properly belong in this book on the effects of deposited radionuclides. However, it is part of a continuum and cannot be separated from work on radionuclides deposited in the body.

in the cogent areas of Utah and Nevada that included "exposed" and "not exposed" groups and a separate control population from Graham County in southeastern Arizona, an area that received practically no fallout from the NTS. All children of the subject communities between the ages of eleven and eighteen years attending junior or senior high school were screened by a team of three physicians in the fall of 1965. Each physician independently examined each child. In 1966-1967, the area was extended to include Lincoln County, Nevada, close to the NTS but with a small population spread over ten thousand square miles. Children with suspected abnormalities were referred to an expert review panel. This process continued to at least 1968. A total of 2,048 children from Utah and 1,440 from Arizona were studied. Of these, 71 from Utah and 25 from Arizona showed suspected thyroid abnormalities. The review panel characterized 31 (22 from Utah and 9 from Arizona) as containing single or multiple thyroid nodules. There was careful analysis of demographic features of all groups. The frequency of nodularity was equal between the "exposed" and "not exposed" groups in southwestern Utah; they were also no higher than in the control group in Arizona.

A later report that included as authors many members of the review panel from the PHS study (Rallison et al. 1974) expanded the group to 5,179 children. The conclusions were the same, viz., no significant difference in any type of thyroid disease between exposed and unexposed groups.^(a) The report was repeated with some additional work and more emphasis on thyroid nodularity as a clinical entity in 1975 (Rallison et al. 1975).^(b)

There are the usual problems of relatively small numbers in these studies from the standpoint of epidemiology. Also, it could be argued on the basis of the ten-year latent period seen in the Marshallese that the 1962 tests did not have time to express themselves. However, the incidence that seemed to peak at about age seventeen (determined by re-examination) was clearly decreasing toward the close of the study. On balance, it seems unlikely that any striking changes in thyroid structure and function could have been missed. While the data are too sparse to permit confident calculation of a risk rate (Maxon 1983),^(c) they have served their initial purpose.

These reports do not indicate whether or not the surveys turned up any other abnormalities or whether or not the dental survey was ever consummated. There was, however, a considerable effort aimed at leukemia—a recrudescence perhaps of the unpublished report of Weiss mentioned earlier. We will now turn to this.

A definitive study of leukemia, known as the "Lyon Study," was produced in the Department of Family and Community Medicine at the University of Utah (Lyon et al. 1979). The researchers divided the state into "low" and "high" fallout counties on the basis of maps of fallout patterns obtained from the Defense Nuclear Agency and the Energy Research and Development Administration (ERDA). They reviewed all deaths from childhood cancers up to age fifteen

(a) An interesting spin-off of this study was the fact that only 6 of the 201 children found to have thyroid abnormalities knew of their disease prior to examination. The authors urge careful examination of thyroids even in apparently healthy children to get more reliable base-line data for the nation as a whole.

(b) Some of these reports had earlier counterparts in "house documents" such as *Radio-logical Health Data*.

(c) The subject NCRP report has been published as Report No. 80.

years occurring in the entire state between 1944 and 1975, with a separate cohort for those under fifteen between 1951 and 1958. The authors could not distinguish between external exposures and specific isotopes entering via the food chain for the simple reason that isotopic composition was not reported before 1957. This may account for some of the perturbations of the data, since the measure of dose is, thus, quite crude.

For reasons that are quite unknown, the base-line leukemia mortality in the low-exposure cohort in the high-fallout counties was about one-half that in the remainder of the state and in the rest of the United States. Thus, any increased incidence presumed to be due to exposure to fallout in these counties is above an unusually low base line. The "high-fallout" counties were southern and eastern and are all rural in nature. The remaining "low-fallout" counties were northern and western and were more urbanized; they contained 90% of the population. The cancers were divided into two categories: leukemias and other childhood neoplasms.

The picture of leukemia incidence in the Lyon Study is given in figure 12.14A according to years of occurrence and according to exposure cohorts in figure 12.14B.

FIGURE 12.14A. Adjusted leukemia mortality rates per 100,000 population according to year of occurrence for counties with high and low fallout. (Redrawn from Lyon et al., 1979. Reprinted with permission of the *New England Journal of Medicine*, Waltham, Massachusetts, copyright 1979.)

Mortality from leukemia increased by 2.44 times in the high-exposure cohort residing in high-fallout counties and was highest in ten- to fourteen-year-old children. A gamma dose of 6 to 10 rad to the bone marrow was calculated to be needed to produce this excess of leukemia. Other childhood cancers seemed to

FIGURE 12.14B. Adjusted leukemia mortality rates per 100,000 population for high-exposure and low-exposure cohorts for counties with high and low fallout. (Redrawn from Lyon et al. 1979. Reprinted with permission of the *New England Journal of Medicine*, Waltham, Massachusetts, copyright 1979.)

decrease during this period. Despite the apparent circumstantial evidence, the authors state "the increase in leukemia deaths could be due to fallout or to some other unexplained factor" (Lyon et al. 1979, p. 397).

As with most epidemiologic studies involving rather small and shifting populations (the high-fallout areas have been losing population steadily since the 1940s, especially in the younger age groups), there are problems with drawing any conclusions. Land, at the National Cancer Institute (Land 1979), takes the position that the control group should be greatly expanded. He is also troubled by the possible interpretation of the data (which he demonstrates) that fallout produced *both* an increase in leukemia mortality and a decrease in other childhood cancers during those years. It is indeed notable that the primary effect in the cohort study was to bring the rate up to that in the low-fallout counties and slightly above that in the rest of the United States. Does this have anything to do with fallout or radiation, or is it quite a different phenomenon? Land reserves judgment as to causation versus artifactual explanations.

James Enstrom, a cancer epidemiologist at UCLA and program director for cancer control epidemiology at the UCLA Comprehensive Cancer Center, was sufficiently concerned over the possible unwarranted extrapolation of the Lyon Study in the public mind that he wrote a detailed article for the *Los Angeles Times* (Enstrom 1979). He expanded upon it in the report on the Baneberry incident (Enstrom 1980). He states, "Once all of the available statistical evidence is considered and these findings put into perspective, however, no reasonable person could conclude that nuclear fall-out from Nevada has caused any excess leukemia mortality." He considers that at no time during the total period of analysis (1944 through 1975) was the leukemia rate in the high-fallout counties

truly different from rates of Utah or the rest of the United States. Also, leukemia in southern Utah comprised only about 1% of the reported deaths under fifteen years of age, while they comprise about 2% in an average Utah population. He raises other questions, e.g., Were the diagnoses reliable? (The number of board-certified specialists in the high-fallout counties is considerably lower than in the more urbanized areas.)^(a) Radiation doses were never measured in the individuals succumbing to leukemia to see if they were higher than in those that did not.

Klauber (1980) discussed other problems with the study, including migration, time trends, statistical significance, etc. He does not disown the tentative conclusions but joined others in recommending caution, particularly because of the tendency for cancer mortality rates to vary widely with time in small populations.

Since these studies were, at best, equivocal for leukemia and clearly negative for thyroid changes, there was agitation to mount a much larger, more comprehensive study. The Bureau of Radiological Health of the PHS undertook a feasibility study for such a broader investigation, one including the entire populations of Utah, Nevada, and Arizona (Hoffman, Harlow, and Tully 1981). They addressed, among other problems, the knotty question of locating and resurveying the previously studied groups. The report gives an excellent review of the work done from 1964 on under their auspices. The test cases put into the study indicated that it would be feasible to conduct a full-scale follow-up, but only if the strengths and weaknesses of various options were fully appreciated.

So far as this author can find, personnel and funds that might have been thrown into such a follow-up study have had to be diverted to the events we will describe under the heading "People—Phase III." However, investigators at the National Cancer Institute did follow up using cancer mortality data from the National Center for Health Statistics and published a complete review of the enterprise (Land, McKay, and Machado 1984). This very recent re-examination concludes that there is "no pattern of temporal and geographic variation in risk supportive of the reported association [between childhood leukemia and radioactive fallout]." It is suggested that "the purported association merely reflects an anomalously low leukemia rate in Southern Utah during the period 1944 to 1949." This addition is not a substitute for the very broad investigation envisaged in the feasibility study, but it appears to represent the most that can be concluded from the data at hand.

3. People—Phase III—Litigation

It was probably inevitable that contention, bitterness, and litigation should come to the events and the people we have been describing. It was a logical extension of public apprehension regarding nuclear energy and nuclear weapons. Details do not belong in a book devoted to scientific research on the health effects of radioactive materials. Also, obviously we cannot say anything about items still under litigation. However, some samples of the activities are pertinent.

First, let us put to rest the mistaken notion that there were no proper standards for fallout at the time of the tests most involved in the litigation. Section VII devotes considerable space to standards for fallout and describes in detail the recommendations in place under AEC auspices in 1953. The problems were

(a) This could, of course, work both ways if there were many cases missed during the periods of high fallout.

not primarily those of knowing how much was too much but of predicting where the fallout would go and in what quantities, as well as deploying personnel and measuring devices in the right place at the right time. Collection of global fallout was easier. Establishing the real behavior of clouds wandering over hundreds to thousands of square miles of terrain was a new and very challenging task.

Second, the onset of litigation stimulated much new research, both archival and experimental.

One thing is quite certain. The role of radionuclides in the possible production of radiation doses and possible health effects was now receiving emphasis whether it played an important role or not (see discussion of "the hidden dose" in section VIII).

The agitation seems to have been sparked by some lawyers, notably Stewart Udall of Arizona. The time was ripe. Cancer incidence in the populations exposed in the 1951-1962 era was bound to increase since this group was now entering the age range when cancer incidence normally peaks. It is not surprising that many of the exposed individuals began to wonder if their cancer or that of family members had been caused by the increased radiation levels during the tests. There was also a residuum of resentment at events of the earlier years variously depicted as "being exposed without consent or knowledge," "withholding of information," on up to culpable negligence on the part of the U.S. government.

The process was brought into focus by the Radiation Exposure Compensation Act of 1981 (#S 1483) introduced in the U.S. Senate under the sponsorship of Senator Orin Hatch of Utah. The act came before the Senate Committee on Labor and Human Resources; it was revised and reviewed in 1982. Its primary objective was to "construct a proper remedy" so that those whose cancer was clearly related to fallout would be compensated by a just and compassionate government. The most thorny question has been and continues to be the establishment of criteria for "clearly related to fallout." Since there is no way to distinguish between a cancer produced by radiation and a "natural" cancer, a new approach called the *probability of causation* was added to the conventional ones already being used. This approach was formulated by Victor Bond at BNL and championed by the NCRP (Bond 1981a,b, 1982). The formulation calculates the odds that radiation was causative as follows:

$$\frac{R_R}{R_N + R_R + R_O + R_A}$$

where R_R is the risk of cancer from a given dose of fallout radiation in a specific situation; R_N is the natural risk of the particular type of cancer; R_O is the risk from other radiation exposures, such as medical diagnosis and treatment; and R_A is the risk of that cancer from other carcinogenic agents or processes, either environmental or occupational. Theoretically, all that is needed is a decision as to the level of odds (i.e., the ratio) above which compensation should be guaranteed. In practice, the quantitation of risks in the variety of situations encountered in these cases is far from easy.^(a) Nevertheless, the idea is interesting

(a) It could be imagined also that if part of the radiation dose was external and part from internally deposited radionuclides, and if the risks were different, two factors for R_R might be needed. However, Bond and most others using the formulation consider the main risk to be from the external dose and neglect the internal dose.

since, otherwise, compensation might get completely out of hand and radiation become nominally responsible for almost any cancer in any individual who could prove exposure. The costs could be in the billions of dollars.

With potential costs of such magnitude and an atmosphere of bitterness and acrimony developing, the U.S. government through its Department of Energy organized the Coordination and Information Center in Las Vegas described in chapter 11. The Offsite Radiation Exposure Review Project under the Nevada Operations Office of the DOE was also organized. The project and deputy project managers are R. W. Newman and M. Page, Jr., respectively. There was close coordination with the National Laboratories (particularly LLL), the firms involved in the engineering aspects of the tests (e.g., REECO, and Holmes and Narver), and also with other government agencies (e.g., DoD and EPA). The purpose was a complete review and recapitulation of all pertinent data and, if possible, reinterpretation of doses in the light of new knowledge.

A central place in the process has been occupied by the Dose Assessment Advisory Group (DAAG) with Bruce Church as project officer. This sixteen-member advisory group, chaired until recently by Robert Moseley, a radiologist from the University of New Mexico, is broadly based with physicists, radiobiologists, toxicologists, health physicists, epidemiologists, people from the Disease Control Centers, a lawyer,^(a) and a medical school dean. They are receiving almost as much testimony as the Joint Committee on Atomic Energy of the Congress received in the 1950s and 1960s. Lawrence Livermore National Laboratory has been especially active in supplying data and penetrating analyses for both external and internal dose.

We will consider some recent testimony to the DAAG presently. However, several other events should be discussed first since they took place earlier; all are related and bear on the same basic problems.

As part of the review process, an important capsule summary of research on internal emitters stimulated by and bearing on the problems of fallout was prepared by Book and Goldman (1983) at the Laboratory of Energy Related Health Research at the University of California at Davis. This does not attempt to introduce new material but is a cogent and succinct summary.^(b)

During 1979-1980, Bernard Shleien, at the Bureau of Radiological Health, Food and Drug Administration, reviewed all possible measurements of external radiation to the approximately 188,000 persons around NTS exposed to test-generated fallout (Shleien 1981b). The highest cumulative exposure at a populated site was 17.5 R, with fourteen persons receiving over 17 R, calculated as exposure to infinity. The cumulative infinity exposures and number of persons in each dose range as computed by Shleien are shown in table 12.12. Obviously, a majority of persons in this tabulation, estimated by Shleien as about 157,000, received external gamma doses below 0.5 R per annum, the accepted maximum permissible dose for individual members of the public.

(a) It is not clear to this author how a lawyer can help technically with radiation dose assessment, but perhaps he can advise on the evidentiary value of different types of information.

(b) As indicated at the beginning of this chapter, this compendium has been used at many junctures in this chapter, particularly for reference reminders, and the author is most grateful to Dr. Goldman for supplying a copy.

TABLE 12.12. Offsite NTS Cumulative Infinity Exposure (in R)

Cumulative Infinity ^{***} Exposure (R)	Number of Persons in Exposed Group
>17.0	14*
9.0-16.99	17**
8.0-8.99	769
7.0-7.99	10
6.0-6.99	6,563
5.0-5.99	165
4.0-4.99	114
3.0-3.99	2,999
2.0-2.99	766
1.0-1.99	17,889
0.5-0.99	2,420
<0.5	156,756

*Varied from 2-14 persons.

**As noted in the text, previously published reports (TMC 1959) give higher external gamma measurements (or estimates) than corroborated in this study for several locations. These earlier reports would indicate that between 5 and 550 persons resided at populated sites that could have experienced a cumulative infinity exposure of greater than 10 R.

Source: Modified from Shleien 1981b. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1981.

Collective exposure commitments in this population ran from 1,700 Person-R for Lincoln Mine with a population of 200, to 35,000 Person-R for St. George with a population of 5,000. Las Vegas showed 16,900 Person-R for a population of 60,000 or about 0.28 R per person.

A far-ranging review of external radiation dose estimates offsite and a summary of the environmental monitoring procedures and results were presented by Wrenn at the sixteenth annual meeting of the NCRP in April 1980 (Wrenn 1981a). He also summarized the new research stimulated by the problems of litigation and the needs for future studies. His conclusions are in the same range as those just reviewed. They include dose rate as well as "infinity doses" and quote conclusions of the Interagency Task Force on Compensation for Radiation Related Illness (Phase I report) that "among the 172,000 residents downwind [of NTS] there might eventually be expected to occur 18 to 40 cancers of which 6 to 16 should be fatal." This estimate utilized risk estimates from the 1980 BEIR report.

A possibly important gap in these reanalyses is the lack of determination of any possible contributions from ingestion or inhalation. As we have already seen, these may be negligible for a majority of radionuclides but cannot be ignored, for iodine, for example. An unexplained anomaly, noted in the table 12.12 footnote, is the difference between the computed external gamma measurements published in 1959 by the Test Managers' Committee to establish fallout doses (Shelton et al. 1959) and those in more recent reports. At several locations, the new work showed lower doses. The communities involved were small, and the effect of the difference on cumulative overall doses is small. No explanation is apparent. It may lie in matters of interpolation between communities in which no actual measurements were made (Ansbaugh 1979).

An important further addition to the dosimetry, again the external dose, was based not on reanalysis of the old maps and records but on measurements of residual ^{137}Cs and plutonium in soil (Beck and Krey 1983). This was a project of the Environmental Measurements Laboratory (EML), formerly Health and Safety Laboratory (HASL), in New York. They took soil samples from over 150 sites, mostly grass-covered lawns in towns or on farms that were "verified through local sources to have been undisturbed for at least 30 years except for watering and minor maintenance." It was reasoned that these would give as clear a picture as possible of the total deposition and stratification of fallout radionuclides with time. From eight to ten core samples were taken at each of the 150 sites. Analyses were made of the 662-keV gamma-ray from ^{137}Cs at several depths up to 30 cm, and radiochemical analyses were performed for ^{239}Pu plus ^{240}Pu , and for the mass isotopic composition. Many additional sites were surveyed by in-situ gamma spectrometry without the hassle of getting a good soil sample.

Global fallout had contributed significantly more of these isotopes than the local NTS fallout. Therefore, it was necessary to ascertain what portion of each sample activity represented NTS fallout. This was made possible by the difference in the $^{240}\text{Pu}/^{239}\text{Pu}$ ratio between NTS and global fallout. It was much higher for global fallout from the high-yield Pacific tests.

A comparison of the integral exposure estimated by the soil core method to that from monitoring data is given in table 12.13A. Note the very reasonable agreement between the two disparate methods. Estimations of exposures to both individuals (population weighted) and populations obtained by this method are shown in table 12.13B.

TABLE 12.13A. Comparison of Integral Exposure Estimates with Estimates [from soil cores] Based on Monitoring Data Obtained after the Tests at NTS. Values in parentheses are percent uncertainties. The estimated uncertainties in the monitoring data range from ± 40 to 60 percent.

Town	Exposure Estimate (R)

The EML work addresses the fact that average bone doses in Washington County were ten times those from global fallout in the United States, while they were four times greater than for external exposure to fallout in the northern Utah counties.

Beck and Krey conclude that the doses calculated for all areas are below those required to produce a significant mortality excess from leukemia (using

2×10^{-5} per rad as the average lifetime risk for radiogenic leukemia). This is based, of course, on the external gamma dose alone.

At least three other new approaches are seen in the proposals made by McDonald E. Wrenn, University of Utah, as part of his testimony on U.S. Senate Bill #S1483^(a) on October 27, 1981 (Wrenn 1981a). The first approach utilizes measurements of the radioactivity of quartz grains in bricks from houses in the areas of interest. The quartz in the bricks is made slightly more radioactive than in its natural state by the extra gamma flux in the environment from passing and deposited fallout. This is cumulative from the time the brick was removed from the kiln in which it was fired and can be measured by the strength of the stored thermoluminescent signal. Since background radioactivity in these bricks is more or less constant, any excess found in a given location can be considered due to radiation from fallout. Fortunately, the method is quite sensitive and not many bricks are needed from any one location!^(b) Results of this work are not yet available.

A second approach proposed by Wrenn and his colleagues may give a better way to reconstruct the amounts of iodine isotopes in fallout from the different events. Of the several iodine isotopes in fallout, one, ^{129}I , has a half-life of sixteen million years and will, thus, be present indefinitely in any sample in which it can be measured. Fortunately, it is formed in fixed proportion to ^{131}I and can thus indicate amounts of the latter originally present.

The Utah investigators' plan is to use an ultrasensitive technique and measure ^{129}I in the tissue blocks (small samples routinely taken for pathology work) of thyroid tissues stored at the Salt Lake City VA Hospital.^(c) Results are not available yet from these studies either, but if a sufficient geographic spread of samples is available, they should be of considerable interest.

Finally, Wrenn (1981b) proposed to measure the residual plutonium in human tissues similarly stored. The proposal is to select cases that could only have received the plutonium by inhalation of fallout. This will take some doing, and the numbers may be rather small.

We come now to the type of data presented to the DAAG.^(d) Many of the calculations are tied to specific litigants and, therefore, cannot be quoted here. However, much is not enmeshed with the litigations and can be summarized as follows:

1. An in-depth review of the fallout contour maps, the way they were constructed, and some selective rechecks indicated that many of the old contour lines needed modification. This was particularly true of many of the areas designated as "hot spots." Many of these were found in fact not to exist now or ever to have existed, although other hot spots were fully confirmed. These new interpretations were incorporated into revised dose estimates.

(a) The Radiation Exposure Compensation Act.

(b) This is, of course, reminiscent of methodology used by archeologists to measure the age of fired pottery (Wrenn 1981a).

(c) Fortunately, most hospitals keep their pathology tissue blocks available for many years for possible rechecks.

(d) This author is indebted to Marshall Page, Jr., deputy project manager of the Offsite Radiation Exposure Review Project, for copies of typical transcripts of these meetings.

2. Details of the technique used for each community are presented including not just surface fallout but events at various altitudes; numerous maps are presented.
3. There was a thorough review of the lifestyle, agricultural practices, housing, and all similar factors that might bear on dose to the inhabitants through the food chain.
4. Much soil-sample work was done on both old and recently collected samples. This ranged over the country far from the areas of high local fallout.
5. Assessment was made of the dose from internal emitters and external dose to skin, whole body, red bone marrow, lower large intestine, thyroid, kidney, liver, lung, and testis. Also, the probable dose to a fetus in utero was constructed. This was done individually for each litigant and each event, an enormous task done largely by the biology group at LLL. Other tissues were added for certain cases.
6. It was determined which radionuclides contributed certain percentages or more of the dose to selected organs, and the cumulative dose from each was calculated and summed with the others.
7. The nuclides that contribute 1% or more to the thyroid dose were ^{131}I , ^{132}Te , and ^{133}I .
8. The radionuclides contributing 5% or more of the dose to the lower large intestine were ^{239}Np , ^{89}Sr , ^{93}Y , ^{97}Zr , ^{140}Ba , and ^{147}Nd .
9. The radionuclides contributing most to bone marrow dose were ^{89}Sr , ^{90}Sr , ^{131}I , ^{132}Te , ^{137}Cs , and ^{140}Ba . (a)

The analysis sums the dose over all nuclides and all events to which the given litigant had probably been exposed. There was even comparison of different schemes for calculating internal dose, e.g., LLNL, MIRD, ICRP-30, etc. (see chapter 16). Some of the calculated thyroid doses were in the range of 30 to 40 rad. Most of the other internal dose contributions were considerably smaller. Any further details will have to await completion of the work and the end of the litigations, if this ever comes about. (b)

We cannot help but be impressed by the amount of information that could be and has been brought to bear on these specific cases. Whether it will prove

(a) The listings in items 7, 8, and 9 above came from a presentation by Drs. L. R. Anspaugh and Yook Ng, Lawrence Livermore National Laboratory (LLNL) at the January 7, 1983, meeting of the DAAG.

(b) L. R. Anspaugh from LLL and Bruce W. Church from DOE, Nevada Operations Office, have just published historical estimates of external gamma exposures from operations at NTS through Test Hardtack II, 1958 (*Health Physics* 51: 35-51, July 1986). These give a total collective external gamma exposure of 85,000 person-R, with three localities receiving major portions of this (note *collective*, not individual dose, which is much smaller) viz., St. George, Utah; Ely, Nevada; and Las Vegas, Nevada. The figures update those given herein. Also, the authors indicate that this is a part of a seven-year project to determine radiation doses received by residents in the region of NTS. They also stress that the data do not include any consideration of inhalation or ingestion of radionuclides. This must await completion of a major project under way to reconstruct and report "all significant pathways of exposure and dose." Thus, we will still have to wait a while for answers to some of the major questions raised in this chapter.

sufficient to render an unequivocal, or at least a satisfactory judgment of the probability of harm, only the future can tell. (a,b)

- (a) It should be noted that on January 4, 1983, President Reagan signed a bill directing the government to "study the issue more carefully" (Smith 1983). The Department of Health and Human Services was ordered "to develop better estimates of the radiation doses to human thyroids from the fallout, and to relate the doses to a probable incidence of cancer..." (Smith 1983). Further, the department was ordered to prepare statistical tables that indicate the likelihood of contracting cancer after exposure to specific doses of ionizing radiation over the range 1 millirad to 1,000 rad. It was also required that the data be presented in a manner that would allow determination of the probability of causation.

The idea is obviously to prepare a model for determining how much compensation each exposed individual should get—a laudable objective.

The first provision is simply an extension of the work already under way and described in the section above. In view of the enormous effort already expended, it is hard to see how really new information can be found unless some of the more novel approaches described in this chapter bring in unexpected results. The order to cover the range from 1 millirad to more than 1,000 rad is asking for the solution by fiat of the problem of dose-effect relationships that the biomedical community has been struggling with for decades. (This may be why President Reagan is said to have signed the bill "reluctantly.") Such statistical tables all in one place will undoubtedly be useful, but the low-dose range will have to be done by extrapolation, just as it is now. If the lawmakers really want a better solution to the low-dose problem, generous support of thorough research into basic biological phenomena might hold greater promise in the long run.

- (b) On May 9, 1984, Judge Bruce Jenkins in Salt Lake City ruled that ten cases of cancer in the exposed civilian population in Utah had been caused by the radiation from fallout radionuclides from the NTS and that the U.S. government had "unreasonably placed plaintiffs or their predecessors at risk of injury" (Smith 1984). The conclusion involved seven cases of leukemia and one each of breast cancer, thyroid cancer, and lymphoma. Obviously, the ruling can be expected to apply to dozens of similar claims and have "enormous legal and economic repercussions" (Smith 1984).

The ruling criticizes especially the lack of monitoring of radiation exposures of vulnerable individuals, particularly children, by the use of film badges, counting of thyroids, or whole-body or blood counts. It also cites the potential for "hot spots," discussed repeatedly in the reports and in the preceding pages of this chapter, for creating radiation doses considerably higher than those stated publicly as having occurred. It also states that more was known about the amount of strontium deposited in the bones of the people of Nepal, Norway, or Austria than of the residents of St. George, Cedar City, or Fredonia, which lay directly in the path of fallout.

It may be that all that is left now is determination of the size of the compensation for the many other potential cases. Yet, the scientific work continues, as do differences of opinion as to what the scientific as opposed to legal conclusions should be. This is still for the future to tell. In any event, the whole episode has stimulated scientific detective work that will be useful in many other connections and has advanced significantly our knowledge of the knotty problems of the long-term effects of low-level radiation exposures. Only a full explanation of the mechanism of radiation-induced cancer and the doses necessary can resolve the scientific question. Yet, the enormous scientific efforts stimulated by the problems of fallout and detailed in this and following chapters have great value irrespective of any legal decisions on blame for injury or its causation.

4. Sheep

A controversy of proportions almost comparable to that described above for human populations around NTS arose in connection with farm and range animals. It did very little to further our understanding of the health effects of radionuclides but was of consuming importance to those concerned. We will review it briefly with emphasis on the scientific aspects.

We saw in the discussion of the first shot, Trinity, that cattle could receive beta burns from deposition of fallout radionuclides on their backs. However, as we will see in chapter 13, these did relatively little damage to the overall health of the animals. In the earlier days of operation of NTS, offsite ranchers made claims (and received settlements) for injury to their cattle from fallout (e.g., U.S. Congress 1955). It was customary to keep a wary eye out for wandering cattle near the test site when shots were planned, but, as the dimensions grew, so did the difficulty of such surveys.

The incident (or incidents) of concern here involved the unexplained deaths of hundreds of sheep and lambs, particularly at lambing time, in and near ranching communities of southeast Utah (e.g., Cedar City). This occurred in the spring and summer of 1953. Fallout from two tests in the Upshot-Knothole series (Shot "Nancy," 24.4 kt fired on March 24, 1953; and Shot "Harry," 32.4 kt fired on May 19, 1953) were accused of being responsible for the sheep and lamb deaths. The exposures may have occurred partly during the "trail back" process from Nevada to Utah, partly at the site of lambing.

The AEC and the state of Utah sent in veterinarians to examine the animals. They were joined by representatives of the Bureau of Animal Industry of the U.S. Department of Agriculture, the PHS, and the U.S. Army Veterinary Corps. Some of these individuals had had in-depth experience in radiation pathology; others had none. A large number of the sheep deaths had already occurred by the time this cadre of experts was convened. Hence, firsthand observation by the experts was rare.

The lesions that were observed did not in general resemble the classic lesions associated with radiation exposure. They should have, because many of the deaths occurred within relatively short periods after the exposure, and exposures massive enough to be fatal in a short period would be expected to show definite effects in a majority of the animals. Examination of animals dying shortly afterward and said by the owners to resemble those that died earlier, gave no evidence of classic radiation damage. The absence of damage was confirmed pathologically by an examination of the tissues of animals that were selected by the owners as representative of their damaged flocks (Bustad et al. 1953).

From this point on, the story becomes more and more confused and complex. It had been a dry cold winter, and the animals were in poor physical condition. It was also considered possible that the animals had drunk "bad water" en route from winter range. They were undernourished. There was a severe snowstorm at lambing time. Could these circumstances have made the animals unusually sensitive to radiation? To check this out, investigators at Hanford undertook a special experiment as a supplement to the large laboratory/field experiment described in chapter 8. They mounted "The Triple Radiation Assault" experiment (George, Hackett, and Bustad 1957). Sheep from the laboratory herd were subjected to a combination of starvation, application of plaques of beta-emitting radionuclides to cause beta burns, oral administration of ^{131}I , and whole-body gamma irradiation. While there was no doubt that this combination

added insult to injury, the type of synergism of effects required to explain the sheep deaths was not evident.

The issue, as a public and legal concern, subsided for a number of years but was resurrected in the late 1970s. Gastrointestinal-tract damage from ingestion of fission products was proposed as the central cause (Knapp 1979), despite the fact that this development would have been accompanied by massive bouts of diarrhea, both on the trail and at Cedar City.^(a) It was not. There were problems with reconstructing the dose (Koranda, Anspaugh, and Ng 1982). The media began a constant drum beat (Holden, 1980; Smith 1982 a, b).

Litigation by the ranchers against the U.S. government in 1956 had resulted in a verdict in favor of the government. In 1982, the case was reopened against the government as well as against some individual scientists, who had served as government witnesses in the previous trial, on grounds of withholding evidence, concealing data, etc. A verdict was rendered in favor of the plaintiffs by the judge who had heard the case in 1956. However, his verdict was overturned by a three-judge panel of the Tenth U.S. Court of Appeals. The plaintiffs then appealed to the entire Court of Appeals, but the entire panel affirmed the decision of the three judges. Upon further appeal, in January 1986, the U.S. Supreme Court denied further review of the matter, thus upholding the decision of the Court of Appeals. The U.S. District Court in Salt Lake City dismissed the plaintiff's action against the individual scientists "with prejudice on the merits" in March 1986.

Unfortunately, and despite much digging, little new scientific information was uncovered in these many-layered proceedings. Any further discussion of this matter is considered inappropriate to a book devoted to scientific research.

E. Onsite Exposures

1. Workers

Onsite exposure problems with workers in the various civilian organizations at NTS appear to have been relatively well controlled. The limits for worker exposure onsite were set in the very first series, Buster-Jangle, at approximately the level used in AEC contractor plants. Ordinarily this limit was 3 R (gamma radiation only) for the whole series with 3.9 R allowed in special cases (see section on Standards for Fallout).^(b) This compared well to the then-current plant limits of 0.3 R per week. Much the same operational limit was applied for Upshot-Knothole in the next year. It was 3 R based on the three-month operational period. This carried on to subsequent test series with a few exceptions.

The development and acceptance of these limits by the various components of the test organizations is traced series-by-series and shot-by-shot in the book by Hacker on radiological safety in the nuclear weapons testing program. The limits were designated for external radiation dose from the prompt radiation and the fallout cloud. They were measured by film badges or gamma survey instruments.^(c) *The philosophy that internal dose would automatically be taken*

(a) That is, the gastrointestinal-tract syndrome in acute radiation damage.

(b) No further exposure was permitted individuals who reached this limit.

(c) Recently, the government has sent many individual workers copies of their file of such exposure records.

care of by not exceeding the external limits held full sway. There were occasional bioassays, nose swipes, etc., to check for internal emitter contamination of personnel. In general, the figures resulting from these checks were low enough to validate the basic philosophy. If work was to be done in a known contaminated area, full protective clothing was worn, including respirators. The rules were strict and fairly rigidly enforced. Bioassay procedures were, it seems, regular in these instances,^(a) but this author is not in a position to judge their adequacy.

Thus, records pertinent to possible internal emitter contamination are sparse except for operations with known potential for same (see chapter 14).^(b) Potential problems in this hiatus can be seen. For example, in a review of much of the literature bearing on exposures to low levels of radiation (Marx 1979), the ideas of Alice Stewart are noted, viz., that inhaled or ingested radioactive dust from atomic-bomb blasts produced the leukemias seen in the Japanese, while the solid tumors resulted from the external radiation. This untested hypothesis is more an example of the type of thinking that may have to be dealt with in future reviews of worker health at NTS than of actualities. In general, as we have seen throughout this book, the induction of leukemia by deposited radionuclides is of less significance at low doses than other effects. It is, in general, more likely to result from whole-body external gamma doses.

It cannot be concluded with certainty that internal emitter contamination from earlier deposited radioactivity played no role in later shots at NTS. Workers did enter areas that had contamination residual from earlier operations. However, radioactive decay played an important role in reducing such contamination in terms of short-term or acute effects. It is only around long-term effects from low levels that some questions might be raised.

On the whole, overexposures of NTS workers to radionuclides at NTS do not seem to have been a serious problem.^(c) Hacker's book will give much more detail, including the exceptions.

2. Atomic Veterans

The situation for the atomic veterans is rather different. It involves the military personnel who participated in the many troop exercises and maneuvers in connection with several of the Nevada tests. There were over 250,000 participants from the DoD in the atmospheric nuclear tests carried out between 1945 and 1962 in Nevada and in the Pacific. Many of these were in Nevada for exercises termed "Desert Rock I, II . . ." etc. These exercises involved a much more intimate relation to the devices than in the Pacific since the yields were smaller and the military wished to have troops gain firsthand experience with possible nuclear artillery, etc. They are described in considerable detail by Hacker. Sometimes there was more than one Desert Rock exercise in an NTS series. The number of participants was fairly large, and the shots were not always small. Desert Rock V, for example, (associated with the Upshot-Knothole series) involved over thirteen thousand troops in mock battles and another two

(a) Such information is collected in the Las Vegas library described earlier.

(b) Exposure records from film badges, etc., are reasonably complete.

(c) Many of the old-time test personnel have made it a point to get whole-body counts at intervals. Andrews (1985) reports that his own counts indicated essentially no detectable retention of radionuclides associated with the tests.

thousand to run the camp. The radiation safety standards for the earlier Desert Rock events were pegged at the same level as for AEC contractor workers. However, the military wanted their troops to have closer encounters with atomic weapons and requested higher levels, e.g., 6 R for an exercise (Hacker undated). This was not accepted easily by AEC, but finally it was agreed that the military could operate with somewhat higher doses if they let everyone know that the DoD was taking the responsibility.^(a)

There was a problem that, beginning with the Upshot-Knothole series, sampling of the clouds of fallout and debris was done by manned planes rather than by drones. The military sought to allow aviators selected for this duty to receive exposures of 20 R or even higher so long as there was no new exposure for two years (Hacker undated). Also, there were circumstances where volunteers were stationed much closer to ground zero than a 3-R limit would permit.

Again, these dose limits were for external gamma radiation. The chances of inhalation or ingestion were obviously greater in some of these operations than for civilian workers. Troops describe being surrounded by clouds of dust in their trenches. While it is assumed that the cloud-sampling aviators wore full protective clothing and respirators, the chances of leakage, carelessness, or excess zeal to collect the precious cloud samples cannot be denied.

In 1977, the PHS Centers for Disease Control in Atlanta discovered a "cluster" of possible cases of leukemia among military participants in an especially dirty shot in the Plumbbob series in 1957, viz., Shot "Smoky." Without hesitation, DoD began a wide-range program to identify participants in the various exercises. The documentation was undertaken by the Defense Nuclear Agency (DNA), and the program was termed "Nuclear Test Personnel Review."

The word was spread through various media for participants in any of the atmospheric nuclear tests to contact the DNA. Also, servicemen who could establish participation in the exercises and had health problems were advised to contact the nearest Veterans Administration Hospital for a free physical examination. If they had leukemia or other forms of malignancy, they were essentially guaranteed care at a government facility.

Unfortunately, large gaps have occurred in the records of many servicemen due to a disastrous fire in a storage facility in St. Louis some years ago. Thus, the objective of a neat reconstruction of exactly where all individuals were, their probable doses, and thus the probability of causation of their cancer (see section V D), has not been realized in full. It may well be that there will be blanket payments based on very broad criteria.

We again have the dilemma of the contribution of internal emitters. Obviously, there was more reason to anticipate a role of radionuclides in the military than in the civilian worker exposures.

Relatively little new research has been mounted to address this question. Most of the evidence comes from retrospection. A project by the Advanced Research and Applications Corporation (Lee et al. 1983) has calculated committed organ doses received by selected military test personnel. The only doses of significance came from the notorious Bravo test in the Pacific (see section III D). There have been other such analyses using the same techniques as we described for the Utah-Nevada civilian residents. The continuity of records is, of course, a

(a) This nuance has frequently been forgotten.

much greater problem than for the relatively stable populations of rural Utah and Nevada. In 1985, a National Research Council Report (Smith 1985) concluded that there was "no consistent or statistically significant evidence for an increase in leukemia or other malignant disease in nuclear test participants." This report has, of course, been challenged, and the pot still boils.

Only a few measurements for body burden of radionuclides in the exposed military personnel have been made and formally reported. Toohey et al. (1981) used the ANL counting facilities to measure whole-body and thorax gamma-ray emissions and used urinalyses for ^{239}Pu . They measured sixteen former military personnel who were present at Shot Smoky, but could find no evidence of radioactivity above that found in the general population. Probably other such measurements should be made. Also, personnel who had counts done informally should be surveyed formally.

Very recently, it was announced that the British Ministry of Defense had announced a plan to survey twelve thousand servicemen and civilians involved in their nuclear weapons testing in the South Pacific. Evidently there had been claims of abnormally high risks of cancer in this population too (Dickson 1983). They will need to go through the same travail as we have in the United States, including some measures of the possible long-term role of radionuclide ingestion or inhalation.

VI. Nationwide and Worldwide Fallout

A. Introduction

Enough has been said already in this chapter to make it obvious that the summation of the hundreds of tests would produce contamination of the total atmosphere, of the lithosphere, the hydrosphere, and of the biosphere on a global scale. This led to by far the greatest volume of measurements, discussion, argumentation, and concern of any of the aspects of the fallout problem. It also led to much bona fide research regarding phenomena in fallout fields and the biokinetics of fallout radionuclides in man, animals, and the diet. It led to thousands of measurements, whose ultimate objective was to determine concentrations of radionuclides from which amounts in the biosphere could be predicted and other thousands of measurements on suitable samples of biological material from which dose calculations could be made.

The chances of seeing biological effects in the field at the low levels of radioactivity associated with global fallout were small indeed, despite claims to the contrary (see section VIII). Definitive research on biological effects could only be performed in the laboratory using the types of work described in earlier chapters and to be reviewed in chapter 13. Thus, field research in the biomedical area had to be limited largely to biokinetics and was pretty much an extension of that we reviewed in chapter 11 and earlier in this chapter.^(a)

(a) Because of the low levels involved, only postulated longer-term effects of radionuclides were of importance. Acute effects were essentially out of the picture for global fallout from weapons testing.

Nationwide and worldwide fallout problems from weapons testing led also to one of the most serious conflicts between science and society seen since the arguments over evolution and the origin of man. Fueled by fears of nuclear weapons per se, by the fact that the benefits of testing (i.e., improvements in weaponry and the maintenance of "peace through strength") could not be divulged in any detail to the general public, and by fear of unknown long-term biological effects, the issue suddenly became major. As we know, it even entered a presidential campaign. A statesman-like review of these sociopolitical aspects of the problem was presented by Commoner (1958) at a symposium on the Social Aspects of Science at a meeting of the American Association for the Advancement of Science.

Important as they are, little else can be said here on these aspects without straying too far from the purposes of a book devoted to biomedical research.

Fortunately, the entire field of global fallout has been exhaustively documented. The many lengthy hearings held under the auspices of the Joint Committee on Atomic Energy of the U.S. Congress are almost overwhelmingly complete. The 1955 print was 60 pages in length; the 1957 print 2,216 pages, the 1959 print 2,618 pages, etc. If these mammoth volumes were easily available, we would need no other literature citations except for work abroad. However, the hearings are not generally available and something more digestible is needed anyway. A succinct and readable distillation can be found in chapter 14 of Eisenbud's book, *Environmental Radioactivity* (1973). The special problems of transuranic elements in worldwide fallout are summarized well in Hanson's book, *Transuranic Elements in the Environment* (1980).

Between these in volume and in conciseness are the reports of the U.S. National Academy of Sciences' several committees on the Biological Effects of Atomic Radiation (BEAR) done specifically around the problems of fallout (NAS-NRC 1956, 1961, 1963); the report of the Medical Research Council of the United Kingdom (MRC, 1956), also written entirely around the problems of fallout; and the several reports of the United Nations Scientific Committee on the Biological Effects of Atomic Radiation (UNSCEAR 1958 et seq.). In addition, there were, of course, many symposia and hundreds of individual papers on specific aspects.^(a)

With such a plethora of documentation, there is little point in delving deeply into individual facts. Instead, we will concentrate on the historical progression of thought and on the institutions and ideas most prominently involved in the field phases.

B. The Physical Events and Measurements

1. The Events

As described exhaustively in documents such as Glasstone and Dolon's *Effects of Nuclear Weapons* (1977) and Eisenbud's *Environmental Radioactivity* (1973), there are three major classes of fallout: local, tropospheric, and stratospheric. We are concerned here only with the latter two. We saw in earlier sections of this chapter that local fallout is extremely important near to and within up to a few hundred miles of a large burst. Events in the kiloton range inject much radioactivity into the troposphere in which it can be carried over considerable

(a) Selected listings of the contents of BEAR reports and of the entire MRC report are given at the end of this chapter as notes 2 and 3.

distances, e.g., across the continental United States. It descends gradually by convective mixing, or rapidly in rain or snow. The retention time in the troposphere is dependent upon the initial particle size distributions and the presence or absence of storms. It is short in relation to stratospheric retention. With multiple kiloton shots, the tropospheric fallout could add up to large doses of external gamma radiation and significant beta-particle effects. However, for our testing activities, the subject of this section, the tropospheric contribution is small (about 5%) compared to that from the stratospheric reservoir.

Eisenbud cites figures indicating that almost all of the debris and radioactive fission products enter the stratosphere from bursts with a yield of more than about five hundred kilotons. Thus, a large part of the megaton-yield test debris enters the stratosphere. Residence time is not constant and is difficult to establish with certainty. However, by the use of stratospheric sampling with balloons (Project Ashcan), and later by very high-altitude U-2 aircraft, and unique labeling of some of the U.S. tests in the Pacific with ^{185}W , both an approximate inventory and a retention half-time in the stratosphere could be estimated.

In early years, both AEC and UNSCEAR estimated mean residence time in the stratosphere at 5 to 7 yr and the inventory at between 4.3 and 5.5 MCi of mixed fission products. By 1959, the inventory figure was revised to about 0.8 MCi and the mean residence time to twelve to eighteen months. The 1962 estimate was still lower because of the cessation of atmospheric testing and consequent reduction of input and removal by both radioactive decay and exchange to the troposphere. The calculated residence time was 0.7 ± 1 yr.

These figures, of course, have considerable bearing on the prediction of biological dose. Even the extremes of the range do not, however, change the principle that with stratospheric fallout the biological problems are largely the deposition of radionuclides in tissues and organisms and their possible long-term effects, not external radiation doses. Herein lay much of the public apprehension. It was easier to give fairly confident estimates of the external doses from early fallout and their possible effects than to be confident about the risks of cancer from radionuclides in the body some decades hence.

The rest of the physical phenomena can be studied in depth in the references cited. Suffice it to say here that much fine research was done in establishing the behavior of the components of fallout, including the use of the presence of radioactivity as a convenient tracer for the behavior of the components of fallout in the atmosphere, hydrosphere, and lithosphere.^(a)

2. The Measurements

a. The Sunshine Project

Relatively early, the AEC established a secret project to study the fallout that might be expected in a nuclear war. This was a particular interest of AEC Commissioner Willard Libby. The Rand Corporation assembled a group of scientists at Santa Monica, California, to organize the effort. The sunny site of this meeting led to the appellation, "Sunshine Project." Originally there were two laboratories involved, Dr. Libby's laboratory at the University of Chicago and the Lamont Geological Observatory of Columbia University at Palisades, New York.

(a) For meteorological aspects see, for example, discussion by Wexler et al. (1956) at the first Atoms for Peace Conference; the NAS-NRC BEAR reports in 1956 and 1960 (NAS-NRC:1960); also Machta, List, and Hubert (1956).

Gradually, many other AEC laboratories were drawn in, and the program became elaborate and far-flung. Reports appeared first from the Rand Corporation and then as AEC documents. Classification remained in force on much of the work until the pressures of the Congressional hearings and other factors brought the activity into a more open arena.

It was necessary early to pick a few elements out of the welter of fission products and concentrate attention on them. Particular emphasis was placed on ^{90}Sr as a bone seeker of long half-life and considerable abundance in fission and, thus, in fallout; ^{137}Cs , a soft-tissue seeker of comparable abundance; and ^{131}I for reasons already obvious from earlier discussions. The Sunshine Project became especially interested in strontium (both ^{89}Sr and ^{90}Sr) and devised a unit for its concentration, known as the "Sunshine Unit," which was based on the amount of strontium per unit of calcium, since in most systems of interest strontium resembles calcium in its behavior and could be regarded, in a sense, as a diluent to a large calcium pool. Expressed as picocuries (or micro-microcuries) of ^{90}Sr per gram of calcium, one "Sunshine Unit" equaled $1\ \mu\text{Ci/g}$ calcium. In much of the early reporting, strontium data were reported in this unit or in another we will meet presently, the Maximum Permissible Concentration (MPC) Unit.

As the fallout controversy heated up, many observers reacted negatively to the term "Sunshine" for the project and the unit. Not knowing the rather innocent origin of the term, it was interpreted as an attempt by the government to cast the subject in spuriously bright terms, even to imply that fallout was "good for you." The unit was eventually renamed the "Strontium Unit," and the project gradually lost its identity as the participants grew in number and variety.

Key open-literature references to the Sunshine Project and the ideas of Willard Libby are concentrated in 1956. In a paper to the National Academy of Sciences (Libby 1956c), he emphasized soil and biological concentrations of strontium, and coined the term "MPC Unit." This unit was derived from the fact that the MPC of ^{90}Sr in the body, based on toxicity relative to radium (see section VII), was $1\ \mu\text{Ci}$. Since the body contains approximately 1,000 g of calcium, "1 MPC Unit" became $1\ \mu\text{Ci } ^{90}\text{Sr/kg}$ calcium. The amounts found were always much lower, on the order of one one-hundredth or less. The Sunshine Unit, later Strontium Unit, was equivalent to 0.001 MPC unit or 2.2 disintegrations per minute (dpm) $^{90}\text{Sr/g}$ calcium. For some time, strontium was reported in fractions of MPC Units, apparently as a convenient reminder of how far below the maximum permissible level the incoming figures were. This, too, raised a few eyebrows and was considered confusing in the long run, especially since it was tied to a unit, the MPC, that was subject to change.

In a later paper, also in the *Proceedings of the National Academy of Sciences*, Libby summarized current research and, among other things, showed graphically the total ^{90}Sr fallout in specific cities such as Chicago in 1955 and Pittsburgh in 1955–1956 (see figures in the section on strontium), which showed a gradual rise for Chicago, a somewhat steeper rise for Pittsburgh (Libby 1956a).

In a paper published in *Science* (Libby 1956b), a general analysis was made of the results of Project Sunshine with the conclusion "...these local precautions should be entirely adequate and the worldwide health hazards from the present rate of testing are insignificant."

By 1959, Chairman John A. McCone of the AEC announced that there would be regular quarterly releases of all fallout information (McCone 1959). These releases included work from HASL, the various AEC contractors, and many data

from PHS. The first such report included information on *plutonium* collected by Isotopes, Inc. of Westwood, New Jersey, the beginning of a long continued facet of the fallout operation. Mr. McCone emphasized that nothing would be held back so long as he was chairman of the AEC,^(a) quite a shift from the classified status of the early Sunshine reports:

b. General Governmental Involvement

By the time of the 1957 Congressional hearings, the gummed paper tray network described earlier as a brainchild of Eisenbud and colleagues at HASL in New York and an extensive air sampling network were in operation. Reports were made by many AEC groups, both in-house and contractors, by the Naval Research Laboratory, the NRD, the U.S. Department of Agriculture, the Weather Bureau, and by the PHS. The data covered the world in points of origin and involved thousands of pages of detailed documentation. For many years, the PHS issued a monthly summary of the concentrations of many radionuclides in several media as a part of a journal, *Radiological Health Data*. In terms of raw data acquisition, there has probably never been a project that produced any more than these fallout measurements:

The Congressional hearings are the best single source for raw data. Other sources are better for consolidation and interpretation. An early review that preceded even the open literature reports of Libby and the Sunshine Project is one prepared by Howard Andrews (1955). Andrews, a PHS officer, represented the PHS at a large number of tests as described in a previous section. As a member of the Test Managers' Advisory Panel (see earlier sections) he was able to see the broad picture. He reviewed mechanisms of fallout formation, its dynamics, possible effects and radiation dosages and the fact that only 0.5- to 5- μ diameter particles are of any significance for inhalation. He concluded, in the light of the conditions of the day, that the testing program was justified by the defense effort but urged very careful controls.

By 1965, a book-length summary gleaned from a conference at Germantown, Maryland, and sponsored by the Fallout Studies Branch of the AEC's Division of Biology and Medicine (Klement 1965)^(b), mustered nearly one thousand pages, all concerned with physical and chemical measurements of importance to biology and medicine. The last seventeen papers involved biological materials. The table of contents of this volume is shown as note 1 at the end of this chapter. Perusal of this should give a reasonable sample of the variety and breadth of the investigations. And remember, this was only the work pertinent to a branch of AEC concerned primarily with biomedical problems.

c. International Activities

To have extensive coverage of the world for collection of fallout, nearly every nation with scientific capabilities had to play some role. We have already cited

(a) That is, presumably nothing of importance to biological or medical evaluations. The exact statement was, "... I assure this committee most emphatically and unequivocally that so long as I am Chairman of the Atomic Energy Commission I shall not be a party to the suppression or distortion of any information bearing on the safety and health of the American public."

(b) This author is indebted to Dr. Kermit Larson, Seattle, Washington, for providing a copy of this somewhat scarce document.

the extensive U.K. report that covered the entire problem. Not only the United Kingdom, but Argentina, Australia, Austria, Canada, Chile, Denmark, the Federal Republic of Germany, Finland, France, India, Italy, Norway, the Soviet Union, Sweden, Switzerland, Taiwan, United Arab Republic, and many others had extensive sampling networks. Other countries cooperated by allowing collection of samples within their territory. Before the activities ceased, there were even extensive measurements in the Arctic and useful collections from the Antarctic.

The UNSCEAR reports provide ample summaries of the worldwide data and extensive literature citations.^(a) In addition, specific mention is made of work from France (Pellerin et al. 1967) Japan (Izawa, Tsubota, and Nagai 1961), and the Soviet Union (Petrov et al. 1966).

d. Representative Findings

We will review here, very briefly, some of the typical data obtained that pertained to eventual accumulation of fallout radionuclides in the tissues of man, in other components of the biosphere, and in food. We will emphasize the earlier findings and developments.

Among the early unclassified documents is a review of "Radioactive Dust from Nuclear Detonations" prepared by Eisenbud and Harley (1953), which presented results from the fixed (121 stations) and mobile monitoring programs coordinated by HASL with assistance from the U.S. Weather Bureau and DoD. (The mobile teams concentrated on the NTS environs.) The numbers were gross activities reported in disintegrations per minute per square foot. The maxima for the fixed stations were 4,500 at Concordia, Kansas; 3,400 at Norfolk, Nebraska; and 3,600 at Milwaukee, Wisconsin. There was one reading over 2,000 dpm/ft² in upstate New York (in Dexter). Most of the readings in the eastern states were lower. The mobile teams found much higher depositions, but these were more local than nationwide or worldwide fallout. It seems likely that this report, along with its references to earlier published work, was one of the earliest to call attention to the potential biomedical importance of nationwide fallout.^(b)

Three years later, Eisenbud and Harley (1956) updated the figures and expanded them to a worldwide basis. They used largely gummed film and high-walled pots for collection. There were seventeen locations in the continental United States and sixty-two in other parts of the world. They reported mixed fission product activity, ⁹⁰Sr, and gamma dose. The units were millicuries per square meter for the radionuclides and mrad for the gamma dose. The change of units makes comparison to the earlier reports or to the Sunshine Project units difficult. However, the authors comment that all figures are far below those needed to develop a dose approaching the maximum permissible (see section VII).

In the next year, Eisenbud (1957) described the global distribution of ⁹⁰Sr from nuclear detonations with regional summaries of deposition, an estimate of the stratospheric reserve, and the relations between amounts in soil and in milk (more later).

(a) The reader interested in specific countries should consult the list of reports received by the Committee that appears at the front of each UNSCEAR report.

(b) The Sunshine Project was, of course, gathering data in this period, but its reports remained classified or, at least, not generally available until the 1956 Congressional hearings and Commissioner Libby's several summaries.

By this time, the Libby papers had begun to appear, and all the detail was made available in the 1957 Congressional hearings. Air filter data were also added. An example of the gradual increase in ^{90}Sr deposition at two locations (Chicago and Pittsburgh) and worldwide rates are shown in figure 12.15A, B, and C. The upward trend seen in figure 12.15A and B was one of the reasons for the growing concern over worldwide fallout. Other graphs (like figure 12.15C) do not show such a distinct trend and have much wider ranges for the points. An example of the air sampling data, taken also from a relatively early

report by Libby for air in Washington, D.C., is given as figure 12.16. These air sampling procedures were continued over many years for monitoring of both local and global fallout. A typical portable sampler and generator used by the PHS for its offsite surveillance, but not greatly different from those used for more general measurements, is shown in figure 12.17.

The National Air Sampling Network of PHS began in 1953 and was set up to detect trends in the nature and extent of air pollution in the United States. The analysis of radioactivity from fallout was essentially an addition to its original purpose. Beginning with 17 communities, it expanded rapidly so that in three years there were 66; by 1959, 117 sampling sites, 66 in large cities, 51 at nonurban sites. Sampling was also done on an intermittent basis at additional smaller cities so that the grand total was 236 sites. The samples were collected about once in two weeks using a twenty-four-hour sample period, which was found to be as valid statistically as continuous sampling over the entire period and much easier to maintain. The 1959 Congressional hearings give many tables of gross beta activity in air over a

five-year period (pp. 173-185) but present no interpretation of their biological significance except for the obvious fact that they are mostly below $100 \mu\text{Ci}$ (μCi) per cubic meter.

Alexander, Hardy, and Hollister (1960) gave a convenient summary of radioisotopes in soils from worldwide fallout at the symposium described earlier on radioisotopes in the biosphere at the University of Minnesota. Alexander was at the U.S. Department of Agriculture, Hardy at HASL, and Hollister at AEC Headquarters. The sampling was both general and specialized along contours of moderate to heavy rainfall. The variation with latitude is strikingly demonstrated in figure 12.18. Similar variations with latitude were seen in samples from the troposphere, the stratosphere, and in the oceans.

FIGURE 12.18. Millicuries of Sr^{90} per square mile in soil, 1955. (Redrawn from Alexander, Hardy, and Hollister 1960. (a) Reprinted with permission of the University of Minnesota-Twin Cities, Minneapolis, Minnesota, copyright 1960.)

As we saw earlier, the chemistry of sea water produces differences between the cadre of radionuclides remaining in the marine environment compared to the terrestrial. Also, relatively small-sized particles from fallout may remain in surface or near-surface layers of the sea and be moved about by currents. Obviously, a large portion of global fallout has reached the sea, but measurements are much more difficult than for equivalent land areas. Only special expeditions, such as those described in connection with the Pacific tests, have done much more than spot-sample the oceans. Revelle gives a succinct summary of relatively early findings in the 1957 Congressional hearings (pp. 523-535). The story as it progressed can be seen in the NAS-NRC reports on marine radiocology. No startlingly different phenomena have appeared regarding fallout in the oceans. However, we must always remember the potential for significant concentration factors for radionuclides from worldwide fallout in marine organisms; also the fact that because of its relatively high ^{40}K content, the overall specific activity of radionuclides in the oceans may be different from that in terrestrial systems.

C. The Biomedical Aspects of Global Fallout

It was clear from the physical events and measurements that a strenuous effort should be mounted both to determine the amounts of radionuclides from

(a) The open areas in the bar graphs for 70° - 80° and 20° - 30° north latitude represent contributions from potentially anomalous areas. Details are given by the author on p. 8 of the cited reference.

fallout in components of the biosphere and to support reasonable guesses as to their biological significance, i.e., the dose to humans and other organisms. The ubiquitous problem of the long-term effects of very low levels of radiation presented a major obstacle. In the early times, when so much less was known about the biological effects of radiation, there was considerable difficulty in interpretation. We will examine in this section a few of the early and later findings and then summarize the efforts to decide on their biomedical significance.

1. Radionuclide Content of Biological Materials

a. Strontium

Despite its origin in the physical sciences, the Sunshine Project produced fairly copious quantities of information on the concentrations, particularly of ^{90}Sr , in materials of biological significance. In the papers by Libby, already cited, and in an address to the American Association for the Advancement of Science on Friday, October 12, 1956, in Washington, strontium content of human bone, human stillborns, calf bones, and sheep bones was given from work done at Chicago and the Lamont Laboratory. The contents were given as fractions of the MPC Unit defined above. They showed a slowly rising tendency with time between 1953 and 1956, but all the human bone data are in the range of 0.001 to 0.002 MPC Unit, mostly below 0.001, while the figures for calf and sheep bones were in the range of 0.01 to 0.02 MPC Unit. Amounts in Wisconsin cheese ranged to 0.01 MPC Unit; with most of the figures less than 0.005; in Swiss cheese, 0.01 MPC Unit or above; in Chicago milk, from 0.001 to about 0.008 MPC Unit with the majority below 0.005 MPC Unit; and "foreign milk" (many countries including some in the Southern Hemisphere) seldom above 0.003 MPC Unit. The reports were generous with details of both specific figures for each sample location and methodology.

In 1957, the Lamont group (Kulp, Eckelmann, and Schulert 1957) felt ready to focus on strontium in humans in an independent publication. They produced radiochemical analyses (over fifteen hundred samples) of ^{90}Sr in bone from seventeen locations worldwide, arranged for largely through personal contacts and friendships. They concluded that the worldwide average at the time was about $0.12 \mu\text{Ci/g}$ calcium (note the use of micro-microcuries rather than MPC Units) and that this was about one-ten-thousandth of the then-accepted maximum permissible concentration for the body content of humans. There was surprising uniformity in the samples from all stations except those in Chile and Brazil. This indicated that the stratospheric exchange phenomena had already "swamped" the tropospheric concentrations from both Nevada and Soviet tests. They demonstrated clearly an effect of age seen but not as completely in some of the earlier work. Young children had three to four times more ^{90}Sr per gram of calcium in their bones than did adults, which helped to concentrate attention on the young just as occurred for iodine in the thyroid. Finally, it was clear that there could be large deviations from the mean for a given locality, e.g., to as much as ten times the average. This was attributed to diet and helped to stimulate still further investigations of dietary content of ^{90}Sr .

The Los Alamos Health Group sprang into action relatively early in the worldwide fallout work, perhaps because of their close contacts with the tests and the weapons makers. Langham was active in the 1957 and 1959 Congressional hearings (more later). A convenient review of his findings and ideas appeared in the first volume of the then-new journal, *Health Physics* (Langham

1958). He and his colleagues devoted considerable attention to possible future levels of ^{90}Sr in the biosphere and in humans with or without further testing (Langham and Anderson 1958). His postulated average maximum levels in the world population are shown in table 12.14.

With a recommended maximum level in the general population of one-tenth of the occupational limit of $1\ \mu\text{Ci}$ body burden (primarily skeletal) and the fact that the average adult human skeleton contains 1,000 g of calcium, the maximum permissible level of $0.1\ \mu\text{Ci}$ of ^{90}Sr is $0.1\ \mu\text{Ci/kg}$ calcium, or $100\ \text{pCi/g}$ calcium, or 100 Sunshine Units. The predicted levels to 1963 with no further testing (table 12.14) are all less than one-tenth of this figure. They became appreciable fractions of $100\ \text{pCi/g}$ calcium by the year 2050 if testing were to be continued at 10 MT equivalent of fission per year. We will return to these matters.

To save precious space, we will skip many calendar years; hundreds of man-years of work, and millions of dollars of financial input and go to the picture in retrospect as shown by UNSCEAR (1977). Composite results over a decade and a half for dietary ^{90}Sr for New York City and for Denmark are shown in figure 12.19A and B. The amounts in bone are given in huge tables in the report. A glimpse of the picture can be seen in figure 12.20, which compares the Northern and Southern Hemispheres over a twenty-year period.

The consequences of all this are given by UNESCO in terms somewhat different from those in earlier work, viz., as an integration of the radiation dose known as dose commitment (chapter 16 and literature cited therein). The figures, given in millirad, are shown in table 12.15. These figures are a comfortably small fraction of the allowable population dose commitment. However, we should remember that ^{90}Sr is only one of many radionuclides plus small amounts of external radiation contributing to the total dose from global fallout and also that even now (mid-1980s) there is controversy over what the allowable dose commitment to the population should be or should have been.

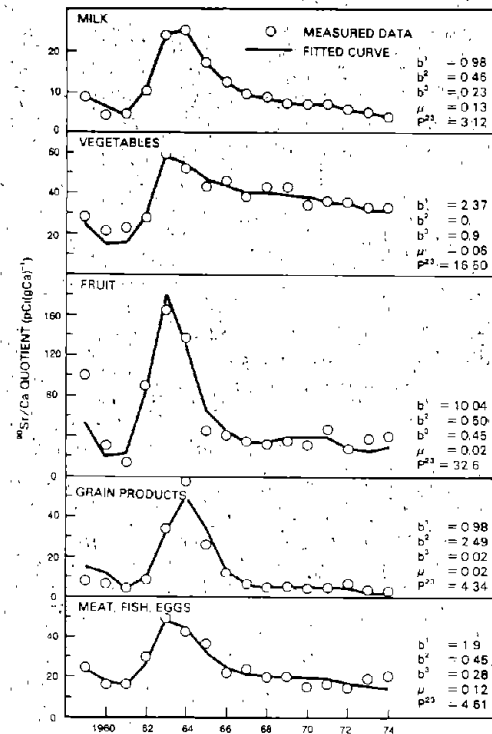

FIGURE 12.19A. (Left) Variation of ^{90}Sr in various diet components in New York City, 1959-1975. The unit for the parameters b_1, b_2, b_3 is $\text{pCi}(\text{gCa})^{-1}$ per mCi km^{-2} . The unit for parameter μ is y^{-1} . The unit for the transfer factor P_{23} is $\text{pCi y}(\text{gCa})^{-1}$ per km^2 . These transfer functions relate the amount in fallout to the amount in diet and are given in more detail in the UNSCEAR report. (Modified slightly from UNSCEAR 1977.)

b. Cesium

There was considerable interest in the possible accumulation of ^{137}Cs from global fallout because of its high yield, moderately long half-life, and localization in soft tissue. It contrasts to the strontium isotopes since the latter are primarily bone seekers and the hazard from them is primarily that of bone cancer and leukemia from irradiation of bone marrow. By contrast, cesium could produce both somatic and genetic effects. (We have already seen its key importance in the long term to local fallout from the Bikini tests.)

A timely summary of ^{137}Cs contamination of the biosphere came from Los Alamos (Langham and Anderson 1958, 1959). Also, there was considerable information presented at the earlier Congressional hearings. Indeed, partly because of the potential for irradiation of gonadal tissues by cesium and other more or less generally distributed radionuclides, the Congressional hearings and other publications of the late 1950s contained dissertations on the potential genetic hazards of radiation and fallout (see, for example, Glass 1957).^(a)

Langham and Anderson estimated a surface deposition of cesium in the north central population belt of about 36 mCi/mi² and a stratospheric reservoir of 4.2 MCi. These are higher than the figures for ^{90}Sr , which were 20 mCi/mi² and 2.3 MCi, respectively. In general, the cesium/strontium activity ratio in fallout is above 1. This does not necessarily mean that cesium presents a greater hazard than strontium. Although the isotope of most concern, ^{137}Cs , has a physical half-life of many years, in fact slightly longer than ^{90}Sr , its retention in the body is

(a) These concerned primarily external sources of radiation.

much shorter (biological half-life of ^{137}Cs is about 70 days in whole body and 140 days in bone, compared to then-current figures of 1.3×10^4 days in whole body and 1.8×10^4 days in bone for ^{90}Sr). It is the potential irradiation of radiosensitive soft tissues, including gonad, that causes cesium to be of any concern.

Cesium is chemically similar to potassium and is similarly metabolized in the body. Therefore, data on incorporation of cesium into the biosphere have tended to be given as ^{137}Cs /potassium ratios, much like the ^{90}Sr /calcium ratios. Cesium enters many foods, including milk.

Early in 1956, the Los Alamos Laboratory began an extensive survey of the ^{137}Cs /potassium ratio in milk supplies throughout the United States. Also, Los Alamos and many other laboratories took advantage of the 0.661-MeV gamma ray from ^{137}Cs to measure the body contents of this isotope in humans and other components of the biosphere. The levels in milk, while they varied, averaged in the late 1950s about 32 pCi (μCi)/g potassium. Highest values were in northern Wisconsin, Minnesota, and North Dakota. The rest of the samples averaged about 20 pCi/g potassium.

Amounts in people were reported as about 41, 44, and 54 pCi/g potassium in the U.S. population in 1956, 1957, and 1958, respectively. The correlation between amounts in people and amounts in milk was very positive, which is illustrated in figure 12.21, taken from the Langham and Anderson papers.

FIGURE 12.21. Correlation of Cs^{137} levels in the U.S. population with levels in milk. (Redrawn from Langham and Anderson 1959. Reprinted with permission of Pergamon Press, Ltd., Elmsford, New York, copyright 1959.)

There was a wide difference among species in the whole-body retention of cesium (^{134}Cs and ^{137}Cs) as seen in the laboratory work of Richmond et al. at Los Alamos, cited in chapter 8. The retention half-times were 1.5 days in the mouse, 6 days in the rat, 19 days in the monkey, 25 days in the dog, and 110 days in man. These differences bespeak the importance of doing field- and survey-type work on people. (a)

The amounts of ^{137}Cs found in people by Langham and Anderson were used to calculate an average radiation dose to bone marrow over seventy years and the possibility of genetic effects. If testing were to continue at a rate of 10 MT of fission per year, the bone marrow dose came to 500 mR. The calculation of genetic changes was, based on the same assumption regarding continuation of testing, 30 to 50 R as the doubling dose for mutations and no threshold for the

(a) Remember the problems Robley Evans had with radium in the rat versus humans described in chapter 1.

genetic response. The increased mutation rate from biospheric contamination with ^{137}Cs was judged to be about 0.5% to 1%.

Interestingly, the potential for leukemogenesis for ^{137}Cs and ^{90}Sr was judged to be about the same if both radionuclides entered the body via soil contamination and subsequent uptake by plants. By contrast, ^{137}Cs was considered only one-fifth as likely to cause leukemia as strontium if entry was by direct contamination of vegetation. Such influences of the pathway were commonly found and stimulated much additional work in both field and laboratory (chapters 13 and 15). Exquisite detail concerning both the levels and importance of cesium isotopes is contained in the several hearings (note especially 1957, p. 751-765).

The Argonne National Laboratory brought its whole-body counter to bear on measurements of cesium in people and also mounted a long-term study of its deposition rate, levels in food, and dose to humans, primarily through the work of P. F. Gustafson. This work continued well into the 1970s and is summarized conveniently by Eisenbud (1973, p. 380 et seq.), along with correlative work at HASL. In October 1968, it was estimated that the Chicago diet introduced 12,300 pCi of ^{137}Cs per year, with milk contributing the largest single portion.

UNSCEAR (1977) estimated that ^{137}Cs absorption had produced a fifty-year dose commitment of 62 mrad in the north temperate zone, 18 mrad in the south temperate zone, and a world population average of 38 mrad.^(a)

An important corollary of the close linkage between cesium and potassium is seen when uptake occurs from soils deficient in potassium. In this case, the cesium may be concentrated to a much greater extent in dietary items. For example, Broseus (1970) reported ^{137}Cs contents in milk from ten to one hundred times normal for a given deposition in areas of Jamaica with potassium-deficient soils.

In the following years, whole-body counters throughout the world followed the ^{137}Cs content of humans and the biosphere. As we did for strontium, we will again skip many years and look at the picture after sufficient time had elapsed to permit a retrospective as well as a prospective view.

The Los Alamos group followed through with whole-body counter measurements of the normal New Mexico population over the period 1956-1977 (Thomas, Anderson, and Richmond 1978; an abstract by Furchner, Wilson, and Richmond 1975; and Richmond and Furchner 1967). The reports build upon other work, cited therein, from several laboratories, including especially Cincinnati (Lewis et al. 1976), Argonne, and Utah (Lloyd and Rundo 1976). The gross trend with over forty whole-body counts per year is seen in figure 12.22, taken from the Los Alamos work.

It is obvious that the concentrations reported in 1958 were considerably exceeded by 1964,^(b) while by 1977, the body contents were about one-fifth of those in the 1950s.

These retrospective analyses pointed to a pronounced time lag in the body burden after each large series of tests. It seemed to be about two years for both the increase and the decrease. Since the retention time of ^{137}Cs in humans is much less than two years, this phenomenon must reflect changes in environmental

(a) It should be noted that, although cesium contributes little to the external radiation dose from fresh fallout; its long physical half-life means that residual cesium contamination on the ground may contribute a considerable portion of the external dose after the shorter-lived radionuclides have decayed away.

(b) The highest average in the United States was 180 pCi/g potassium in 1964, reported by Shukla, Dombrowski, and Cohn (1973) from Brookhaven.

FIGURE 12.22. Whole-body concentration of ^{137}Cs in normal New Mexico population. (Redrawn from Thomas, Anderson, and Richmond 1978.)

concentrations and their effect on the dynamic equilibrium in people. Lewis et al. (1976) summarized the calculated biological half-lives of ^{137}Cs in humans and pointed out the very large range of values. Lloyd and Rundo (1976) addressed this apparent anomaly as another example of environmental transfer effects. They urged that cognizance be taken of the fact that there are two half-lives in these situations, that resulting from physiological processes in people and another resident in the environmental behavior of the radionuclide. They are, of course, separable only by independent laboratory-type measurements.

c. Iodine

As related earlier, it was Van Middlesworth working at Memphis, Tennessee, who first reported in open literature the appearance of radioactive iodine in fresh animal thyroids (1954). This bore more on nationwide than on worldwide fallout, even though it contained samples from both east and west coasts. In 1956, Van Middlesworth gave data on the ^{131}I content of 175 human cases and 1,044 animals over the period from October 1954 to February 1956 (Van Middlesworth 1956). The United States, Canada, England, Germany, and Japan were included in the study. Because of the relatively short radioactive and biological half-lives of ^{131}I , the concentrations show a markedly sawtoothed relationship to time, rising and falling by factors of ten or more over periods of a few months. They thus reflected the tests or series of tests more faithfully and more quickly than either strontium or cesium. Indeed, this rather rapid response with time soon led to interest in iodine concentrations as bellwethers for impending changes in general levels of fallout radioactivity, especially any rapid build-up in the biosphere that might serve as a marker for other radionuclides that were much less easily measured by the techniques of the day.

As described in connection with local and regional fallout, Van Middlesworth used methods for estimating thyroid dose derived for the conditions of the day by Dunning (1956). These considered especially the early contributions of the short half-life iodine isotopes. He calculated doses on the order of 0.15 to 0.40 rep and compared these to the 5,000- to 10,000-rep doses used to treat hyperthyroidism in people; he makes no mention, however, of thyroid cancer that now demands primary attention.

The group at the Oak Ridge Institute of Nuclear Studies (soon the UT-AEC Experimental Farm; see chapter 13), viz., Cyril Comar and R. H. Wasserman,

invested considerable effort in all aspects of iodine in fallout. An early summary done in collaboration with Army and Air Force veterinarians assigned to the laboratory (Trum, Kuhn, and Nold) was published in 1957 (Comar et al. 1957). They studied human thyroids obtained from autopsy material, mostly from persons over fifty years of age, barn-fed cattle, pasture-fed cattle, and milk from the same areas as the cattle. Their conclusions can be reviewed best by presenting the last paragraphs of their paper:

There seems to be little question that the levels of radioiodine introduced into the biological cycles by weapons tests during 1955 and 1956 are far below those that are expected to produce any observable effects. This can best be demonstrated by comparison of levels found with the official maximum permissible values and with findings on the lowest levels of radiation or of iodine-131 that could possibly have produced detectable changes. Such a comparison follows.

- 1) Average peak level observed in man, 0.005 millimicrocurie per gram.
- 2) Maximum permissible level in man for continuous exposure, 15 millimicrocurie per gram.
- 3) Estimated peak level in milk, less than 0.01 millimicrocurie per 100 milliliters.
- 4) Maximum permissible concentration in water for continuing exposure, 3 millimicrocuries per 100 milliliters.
- 5) Estimated average dose to human thyroid from radioiodine during the period January 1955 to December 1956, less than 0.04 rep.
- 6) External dose to neck area in infants and children that has been suggested as cause of later thyroid malignancy, 200 to 725 roentgens.
- 7) Dose to thyroids of sheep on daily intake of iodine-131 at which no damage was observed, 936 roentgens (3 roentgens per week for 6 years).
- 8) Dose to thyroid of sheep on daily intake of iodine-131 at which minor physiological change occurred, 3000 to 5000 roentgens (over 2-1/2 years).

Note that iodine is reported as millimicrocuries ($m\mu\text{Ci}$), i.e., $10^{-3} \mu\text{Ci}$, rather than in micromicrocuries or picocuries ($10^{-6} \mu\text{Ci}$), and as per gram of tissue since there is no analogue of iodine to relate it to, as was done for strontium and for cesium.

The PHS produced much information on iodine, both as a result of measurements from their fallout collection network and from special studies. In 1957, Arthur Wolff reported the iodine activities from small animals necropsied at veterinary clinics in Ohio and Pennsylvania and from cattle and sheep from Pennsylvania, Arizona, Ohio, and Oregon (Wolff 1957). The work was begun before the spring 1956 Pacific tests and continued into the fall of that year. There was a gradual rise in the average iodine content of the collected thyroid glands with a peak in August 1956. Thereafter the levels fell rapidly. Thus, the work proved conclusively a connection between weapons testing and iodine in the thyroid. The small domestic animals had consistently less than the grazing sheep and cattle. The activities were in the range of 0.8 to 0.0008 $m\mu\text{Ci/g}$ thyroid in the cattle, from 2.7 to 0.12 $m\mu\text{Ci/g}$ for sheep, and a maximum of 0.46 $m\mu\text{Ci/g}$ for other animals.^(a) These concentrations agree well with those from the continuing sampling program of Van Middlesworth in the Memphis area (Van Middlesworth 1954) and result in a calculated thyroid dose of "at least 42 millirep" (range 35 to 120) per week. All of the iodine concentrations in animals were considerably above those found in humans in the same areas. Further

(a) In each case, there were many measurements at or below the limit of sensitivity.

work with bovine thyroids from the Montgomery, Alabama, area (Moore, Lambert, and Mills 1964) showed still higher amounts of ^{131}I .

In addition to its work with human thyroid exposures around the NTS, the PHS looked at ^{131}I in thyroids of the general population for correlation with worldwide fallout. Two studies are cited. The first (Visalli and Goldin 1963) concerned thyroids in children in the Winchester, Massachusetts, area. It was partly experimental in that radioiodine-free diets were given to some of the children. It proved conclusively that food, especially milk, was the primary source. The other study (Wellman et al. 1965) measured ^{131}I content of thyroids in ten children in the St. Louis, Missouri, area. (The in-vivo counts were done at New York University [NYU].) The measured amounts were only about one-half those predicted from the dietary content. However, the study was too small to draw general conclusions.

The large Soviet tests in 1961 stimulated several special studies of radioiodine in milk, thyroids, etc. During the temporary moratorium on testing, the iodine isotopes had all but disappeared from the environment except for small quantities of the long-lived members. Soon after the resumption of testing, it was reported that iodine from the Russian tests was present in milk supplies in the United States. The NYU group, including Eisenbud and others who had moved over from HASL, thought it important to assay human thyroid content as soon as feasible. They embarked on a study from hospital autopsy cases in New York City and later in vivo measurements. The first measurement was made about five weeks after the resumption of testing and about ten days after ^{131}I was first detected again in New York City dairy products (Eisenbud et al. 1962). The results were insufficient to establish a distribution of thyroid doses in New York City, but it was possible to estimate dose to the most exposed portion of the population, those who drink the most milk. The integrated dose over the period of the rise and fall of the concentrations in the environment and in thyroids came out to be about 40 mrad in children who drank milk.

In general, these works indicated less significance in humans from iodine isotopes from global fallout than from many other radionuclides. UNSCEAR (1977) gives both integrated milk concentrations and calculated thyroid dose to infants from 1966 to 1974 for locations throughout the world. None are alarming because of the relative radioresistance of the thyroid, but a few approach or exceed the population limit. Later work tended to concentrate more on iodines from reactor releases and from close-in, short-term fallout, areas we have already discussed. Also, much effort was expended on transfer factors and on environmental pathways and vectors that we will meet in chapter 15.

d. Carbon-14

Both fission and fusion devices produce ^{14}C by interaction of neutrons with atmospheric nitrogen. It turns out that the two major types of weapons, as built by the United States at least, yield roughly equal fractions of escaping neutrons, or so it was thought at the time. Therefore, knowing the total energy yield, the escape fraction, and the probabilities of the reactions, those interested could estimate neutron-induced radioactivities. It was the long half-life of ^{14}C (5,780 yr) and its potential incorporation into the vital carbon cycle of the biosphere that led to concern about its presence in global fallout.

Measurements of ^{14}C in fallout and in pertinent materials are prominent in the 1957 Congressional hearings, along with discussion of its possible

significance. The findings were considerably expanded in the 1959 hearings. Since cosmic rays continuously produce ^{14}C in the atmosphere from interaction with nitrogen, the figures are usually presented as ratios of ^{14}C found to that already present in the environment (see, for example, reports from the Naval Research Laboratory in the 1957 hearings [pp. 672-675]) or as excess ^{14}C . The summary given by UNSCEAR (1977) for the period 1954-1980 shows a maximum of close to 70% above the normal amount in the troposphere in 1964 and about 20% excess in the surface ocean, peaking in late 1960s.

Carbon-14, despite its very long physical half-life and quick incorporation into the biosphere, gradually disappears into the bicarbonate and carbonate of the seas and, thus, into the carbonates of rocks and other components of the lithosphere. Hence, most estimates of possible biological effects may be too high by the extent that this sequestering process was or was not accounted for.

Relatively early in the consideration of ^{14}C , Totter, Zelle, and Hollister (1958), all on the staff of the AEC's Division of Biology and Medicine at the time, produced a broad-gauged analysis of the possible hazards of ^{14}C production. First they addressed the possible mutagenic effect of ^{14}C transmutation. (We delve into the entire transmutation problem in some detail in chapter 20. For ^{14}C , it refers to the fact that it decays to nitrogen. Thus, any molecule in which this occurs is suddenly different by some small fraction.) In the calculations of Totter, Zelle, and Hollister, it was concluded "with large uncertainty" that the transmutation effect could possibly contribute about the same number of mutations as the radiation dose from ^{14}C . This was probably an overestimate. Nevertheless, it was the possibility of mutations that captured interest for ^{14}C from global fallout and is still the prime concern.

Totter et al. estimate that bomb ^{14}C released to the date of their paper would produce a worldwide dose of 0.008 mr/yr to every individual in the population and that this would add 1 in 5,340,000 gross physical or mental defects; 1 in 1,400,000 stillbirths and childhood deaths; and 1 in 593,000 embryonic and neonatal deaths. By contrast, normal ^{14}C already present as natural background was calculated to produce 1 in 27,800; 1 in 7,400; and 1 in 1,785 in each of the categories above. This is the hazard, assuming no threshold and a linear dose-response out to about eight thousand years. As in all such calculations, the total number of defects can appear large when multiplied by the population of the world, and especially when projected forward for many thousand years.

Linus Pauling (1958), the chemist turned biologist, felt that Totter et al. and others had underestimated the hazard from ^{14}C . One of the problems seems to be the figures regarding relative production of ^{14}C by fusion compared to fission bombs. Earlier we quoted work indicating about the same escape fraction for neutrons from both types of devices. Pauling uses different figures. He calculated 13.8 kg of ^{14}C per megaton of fusion compared to 1.05 kg per megaton released in fission, or a factor of thirteen difference between the two. On this basis, he concludes that one year of testing (30 MT of fission plus fusion) would be expected to cause a total in the world population of 55,000 children with gross physical or mental defects, 170,000 stillbirths and childhood deaths, and 425,000 embryonic and neonatal deaths. These numbers are about seventeen times larger than those usually estimated for genetic effects from fallout fission products. Pauling recognizes that these are still very small percentages of the total number of such defects that would appear in the world population independent of fallout, and that they may be five times too high or five times too low.

The debate indicates how widely calculations of the effect of ^{14}C can differ. Measurements made both at the earth's surface and in the stratosphere indicated an inventory of ^{14}C of about 4.2×10^5 Ci in 1964, the peak. The individual dose commitment from ^{14}C from the end of atmospheric testing to the year 2000 has been estimated as about 13 mrem (Eisenbud 1973, p. 384). As estimated by UNSCEAR (1977), the individual dose commitments from the ^{14}C from all nuclear testing to *infinite time* are larger; e.g., 103 mrad to gonads, 124 mrad to lung, 414 mrad to bone lining cells, 455 mrad to red bone marrow, and 269 mrad for the whole-body average.^(a) About 10% of these doses would be delivered by the year 2050. While hardly devastating, these levels cannot be said to predict absolutely no significant biological effects, especially genetic changes. If they do occur they, of course, could never be identified because of the relatively high rates of spontaneous mutations and chromosome aberrations and the nonspecificity of the changes.^(b)

e. Tritium

Fairly large quantities of tritium are produced in nuclear reactions both as the result of neutron activation processes and directly in the fusion process. Most of it is in the form of tritiated water (HTO), as discussed in other chapters, and becomes a part of the biosphere. Inventories of tritium were taken early, and much attention was devoted to the residence time of both naturally produced and bomb-produced tritium in the stratosphere. The former is much longer than the latter, explained provisionally by the fact that the injected manmade tritium is, much of it, in the form of ice crystals. The movement of tritium was much used for meteorological investigations. By contrast, little attention was devoted initially to its possible biomedical significance in fallout in contrast to strontium, cesium, iodine, and ^{14}C . This contrast was based, no doubt, upon the results of the laboratory investigations, described elsewhere in this book, that indicated relatively low radiotoxicity for tritium. Also, attention was perforce directed primarily to the potential bad actors.

Nevertheless, the total inventory of tritium was large. UNSCEAR (1977) gives the world's ^3H inventory at 2,900 MCi as of 1970, the bulk of it in the Northern Hemisphere. Much has been done, particularly by the oceanographers, to determine tritium distribution in the sea, its variation with latitude and depth, and its biokinetics. The highest concentration in surface waters of the United States and Canada (eighteen U.S. rivers plus the Ottawa River in Canada) was about 5,000 pCi/l, which occurred in 1964. Dose commitment calculations have been made from these figures. Those to the whole body of the population of the United States and of the Ottawa Valley of Canada were 1.5 and 2.8 mrad per person respectively. Figures for the Southern Hemisphere averaged about 0.2 mrad.

Thus, even though the total inventory of tritium is impressive, the potential for biological effects does indeed appear small compared to many other radionuclides in fallout.

(a) Since ^{14}C is essentially low linear-energy-transfer (LET) radiation, but may have some of the properties of high-LET radiation because of its very low energy, a quality factor of two is suggested for converting these figures to millirem for genetic effects.

(b) A task group of the NCRP has reviewed the possible genetic effects of many radionuclides, including ^{14}C . (NCRP 1987).

2. Food and Water

Many examples of the amounts of fallout radionuclides in food, especially milk, have been given earlier in this chapter. However, the sampling of food and water became such a highly organized and extensive activity that we must pause briefly to review the broad picture. An early summary was produced by the Los Alamos people and helped to organize the field (Anderson et al. 1957).

As always, the volumes from the U.S. Congressional hearings give the most detail and are recommended to any reader wishing to follow specific times, places or investigations. Fortunately, the FRC developed within the Executive Branch of the federal government more or less around the problems of fallout (but also uranium miners, see chapter 3, and general standards, see chapter 16), devoted considerable attention to biomedical aspects of the fallout problem and issued important reports that provide an overview as well as specifics. Report numbers 4 (FRC 1963), 5 (FRC 1964a), 6 (FRC 1964b), and 7 (FRC 1965) all carry much information and discussion relative to food and dietary intake of fallout radionuclides.

In addition, the AEC, PHS, and later the EPA mounted and continued extensive sampling and interpretation programs, and the National Academy of Sciences entered the picture through its Committee on Food Protection of the Food and Nutrition Board (NAS 1973). In fact, the entire agricultural establishment became involved before the furor subsided. Specifics of the parts played by some of these many organizations will be clear from this and the following sections of this chapter.

a. Total Diet

By 1970 (Roeklein, Smedley, and Simpson 1970), the following formal programs were either in operation or had contributed data to the storehouse of information on the concentrations of fallout radionuclides in representative total diets:

1. AEC Health and Safety Laboratory, New York
This group was, as we have seen, among the earliest to collect information on fallout. In March 1960, it began what was known as the Tri-City Study. The cities were New York, Chicago, and San Francisco, the first two representing "wet" areas of the country, the last a "dry" area. Nineteen categories of food from an average diet were analyzed separately for ^{89}Sr and ^{90}Sr , ^{137}Cs and stable calcium. This continued through 1967. The study found that New York and Chicago were reasonably representative of "wet" sections of the country, and San Francisco of the "dry" areas, as gauged by checks of other localities.
2. The U.S. Public Health Service, Bureau of Radiological Health—Radionuclides in Institutional Total Diet Samples (1961–1967)
Monthly samples were collected from boarding schools at different economic levels to represent a seven-day diet for children aged nine to twelve and teenagers aged thirteen to eighteen. Analyses were made for ^{89}Sr , ^{90}Sr , ^{137}Cs , ^{131}I , ^{144}Ce , ^{140}Ba , ^{65}Zn , ^{40}K , ^{226}Ra , and stable calcium. This was continued until 1969 under the Food and Drug Administration (FDA).
3. Consumers Union under Contract to the U.S. Public Health Service (1959–)
This nonprofit organization became deeply involved in the biomedical implications of the fallout from weapons testing. They analyzed complete diets of teenagers for two-week periods in twenty-four cities doing, via contracting laboratories, the same radionuclides as in the PHS survey.

4. U.S. Food and Drug Administration—May 1961–November 1969
Total diet samples were collected quarterly from nine FDA districts. Aliquots were analyzed for ^{137}Cs by gamma-ray spectroscopy and for ^{90}Sr by beta-particle counting. This was continued until 1969.
5. California State Department of Public Health—June 1964–December 1967
Intakes were estimated from house diets of hospitals in twenty different areas of the state. Seven-day-week food samples were collected once each two months and analyzed for ^{89}Sr , ^{90}Sr , ^{137}Cs , ^{141}Ce , ^{144}Ce , ^{95}Zn , and for stable potassium, sodium, strontium, and calcium.
6. Connecticut State Department of Health—March 1963–December 1967
The daily intake was estimated on a sample intended to represent the diet of an eighteen-year-old boy. Samples were collected monthly and analyzed for ^{89}Sr , ^{90}Sr , ^{137}Cs , and stable potassium.
7. Continuation under the Environmental Protection Agency and the Food and Drug Administration—1970–until gradually phased out

It will be noted that most of these programs terminated in the late 1960s because the levels of radioactivity were reaching amounts at or below the limits of sensitivity of all but very specialized methods. Nevertheless, the number of nuclear power plants being projected in the early 1970s spurred efforts for continuation of an analytical capability in case of a major accident. The Institutional Diet Program of the Bureau of Radiological Health of FDA was transferred to the Radiation Office of the EPA. This continued until 1973 when the occurrence of very low levels made the program impractical. This program involved all ten districts of the FDA plus analyses of some imported foods (seafish, shellfish, cheese, fresh fruit, canned fruit, tea, coffee, cocoa powder, and cashew nuts).

A typical picture for ^{90}Sr in the U.S. total diet is shown in table 12.16A, and the contributions of four major categories of food are shown in table 12.16B. The concentrations shown in table 12.16A are at the maximum observed and

TABLE 12.16A. Average Maximum ^{90}Sr Content of U.S. Total Diet (pc $\text{Sr}^{90}/\text{g Ca}$)

	"Wet" Area(a)	"Dry" Area(b)
	— Observed —	
1959	13-18	9
1960	11	4
1961	4-8	3-6
1962	8-13	4-8
1963 (Through March)	10	8
	— Predicted —	
1963	50	35
1964	30	20
1965	20	10

(a) The "wet" area includes all of the eastern and midwestern states west to about the Minnesota-Dakotas border, central Nebraska, the western third of Kansas and of Texas. It also includes the western half of Washington, Oregon, and most of northern California.

(b) The "dry" area includes the balance of those states listed above, plus all of Montana, Wyoming, Colorado, New Mexico, Utah, Arizona, Nevada, and most of Idaho.

predicted. Later figures (FRC 1964b) indicated that the predictions overestimated the maxima somewhat, not only for ⁹⁰Sr but for several other radioisotopes. The picture for several elements and for several components of the diet at this later time is shown in table 12.17. The strontium figures should be compared with table 12.16.

TABLE 12.17. Comparison of Predicted and Observed Levels of Radionuclides Deposited and in the U.S. Diet in 1963*

	"Wet"		"Dry"	
	Pred.	Obs.	Pred.	Obs.
Deposition (mc Sr ⁹⁰ /mi ²)				
Range	30-60		10-30	
Most Probable Value	50	45	20	25
Milk				
Sr ⁹⁰ (pc/liter)	30	25	10	15
Sr ⁸⁹ (pc/liter)	55	50	40	40
Cs ¹³⁷ (pc/liter)	140	125	—	85
Wheat (pc Sr ⁹⁰ /kg wheat)	250	220		
Flour (pc Sr ⁹⁰ /gm Ca)	40	40		
Total Diet (pc Sr ⁹⁰ /gm Ca)	50	30	35	10
New Bone (pc Sr ⁹⁰ /gm Ca)	12	7	9	2
Age 0-4 Bone (pc Sr ⁹⁰ /gm Ca)	5**	5	3**	2

* Except for bone, both predicted and observed values have been rounded to the nearest 5 units for purposes of comparison since this is considered to be more in keeping with the reliability of the estimates.

** Calculated from the observed strontium-90-calcium ratio in the diet.

Source: Reset from FRC 1964b.

Note: For definition of "wet" and "dry" see footnote to table 12.16A.

An important consideration arises in connection with the contribution of various diet categories. From table 12.16B, it is clear that milk contributes the most to strontium intake, especially in the "wet" areas because the average U.S. diet obtains much of its calcium from dairy products. It might be reasoned that switching to grains would reduce the burden of strontium in bone. This is not true because research we will review in more detail in chapters 13 and 15 has shown that there is more discrimination against strontium over calcium in the milk chain than in the cereal chain, so that the same original amount deposited will result in less deposition in bone from milk and dairy products. For these reasons, and despite the much lower consumption of dairy products in many other parts of the world, the strontium bone burden in the Orient, for example, was actually higher than in the United States and western Europe.

It must be realized that the figures given in the tables are subject to variations produced by differences in length of the growing season, agricultural practices, and, of course, the source term, fallout. Items such as fresh fruit and vegetables and fresh milk showed the most geographical variation, while staple items, including meat, were less variable, as were items that usually were composite in origin.

The picture in later years can be seen in results described by Simpson, Baratta, and Jelinek (1974 and 1977) and can be compared to the three ranges for action recommended by the FRC (see section VII). The intake via the total diet was, in 1974, 4.9 pCi/day of ^{137}Cs and 12.9 pCi/day of ^{90}Sr .

There were, of course, individual reports that interpreted the data from these many programs. Typical examples are a symposium held by the Federation of American Societies for Experimental Biology (FASEB 1963) and a review by Shleien (1970), based partly on surveillance data obtained at the Northeastern Radiological Health Laboratory of the Bureau of Radiological Health of the PHS. The maximum fraction of the FRC radiation protection guideline reported by Shleien was 17.8% due to ^{131}I in milk and the largest dose commitment that for ^{90}Sr in bone. It was approximately 10% of that from natural radiation sources.

b. Milk

The literature cited has copious detail on the radionuclide content of milk. We have already illustrated some of it.^(a) For our purposes here, the concentrations in the peak years, as shown in the FRC report (1964b), should be enough (figure 12.23).

It will be noted, as alluded to earlier, that ^{131}I is the most labile since it has the shortest biological and physical half-lives. Cesium-137 builds gradually over the entire period with a peak in mid-1963, and ^{90}Sr is more labile than ^{90}Sr , again because of its shorter half-life (physical in this case).

An interesting glimpse at some of the variations in geographical distribution, this time for ^{90}Sr in milk, is shown in figure 12.24. This represents, of course, a resultant of NTS and global fallout.

The influence of relative rainfall can be seen in the 40-pCi/l figures for parts of Arkansas and Louisiana that stand in contrast to stations not too far to the west but much drier. The 40-pCi/l line in North Dakota probably rests more on

(a) An especially complete summary can be found in the review of the PHS network findings given at the Hanford symposium on iodine (Dahl et al. 1963).

FIGURE 12.23. Average concentration of radionuclides in milk samples from Public Health Service pasteurized milk network (pc/l). (Redrawn from FRC 1964b.)

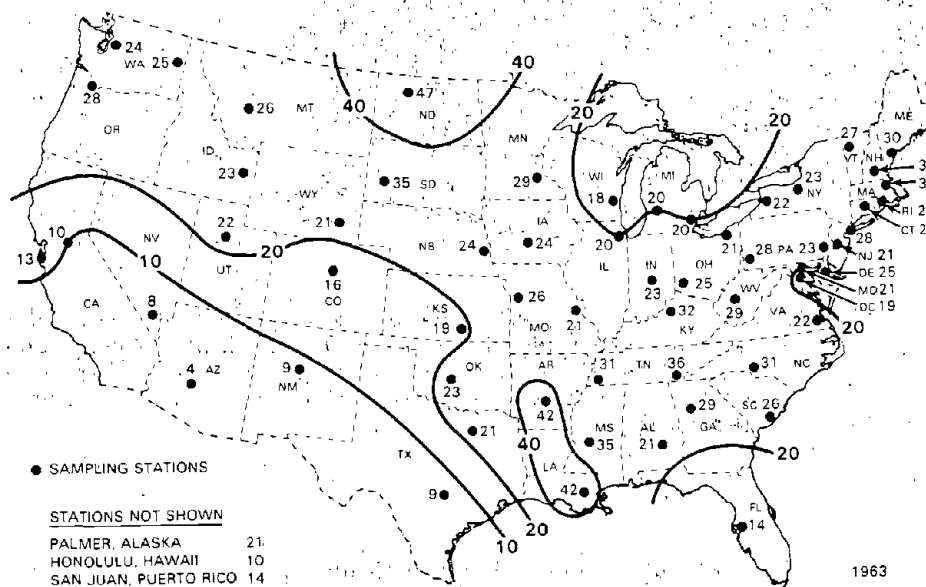

FIGURE 12.24. Strontium-90 concentrations in pasteurized milk. (Redrawn from FRC 1964b.)

transport to the northeast from NTS than on relative rainfall. Much laboratory and field research was built around these various milk sampling networks, and much was learned about the biokinetics of radionuclides in this segment of the ecosystem (chapter 15).

While we glibly quote summaries for milk and other food products, we should not forget that the analyses were far from simple, particularly in the years we are emphasizing. There is far too much natural radioactivity in substances like milk, e.g., from ^{40}K , to permit simple measurements of gross activity. The various isotopes had to be separated chemically and then their radioactivity measured. An example of the separation procedure in action for milk is shown in figure 12.25. This view shows a version of the procedure used at the Southwestern Radiological Health Laboratory in Las Vegas, Nevada. When it is realized that thousands of samples were analyzed by this or somewhat similar procedures, the enormous commitment of the biomedical community to these endeavors can be appreciated.

FIGURE 12.25. View of part of the procedure for analyzing milk for fission product radionuclides as carried out at the U.S. PHS Radiological Health Laboratory, Las Vegas, Nevada. Each radioisotope was measured separately insofar as possible. (Courtesy of Dr. Melvin Carter, Georgia Institute of Technology.)

As a footnote, we might add that the analysis for noble gases was especially laborious. Figure 12.26 shows one of the necessary steps in such a procedure at the same laboratory as shown above for milk. This analysis was probably not of milk, since there was little interest in the amounts of noble gases in milk.

FIGURE 12.26. Part of the procedure for separating out noble gases from fallout fission products as carried out at the Southwestern Regional Radiological Health Laboratory of the U.S. PHS at Las Vegas, Nevada. (Courtesy of Dr. Melvin Carter, Georgia Institute of Technology, who is the operator in this picture.)

c. Wheat, Flour, and Cereals

Table 12.18 shows the progression of ^{90}Sr content of wheat and flour made therefrom over a five-year measured and a two-year predicted period from 1956 to 1965. Comparison to tables already shown points out that wheat contributed one of the highest concentrations of ^{90}Sr of all major foodstuffs at the peak of fallout activity.

The high radioactivity of wheat extended to other radionuclides as well. The reason for this seems to reside in a large contribution of foliar deposition and fewer discrimination factors between source and grain than in the milk pathway. (Note, however, the lower amounts in flour. This may represent partly processing and partly radioactive decay.) Contamination of all cereal grains turned out to be much more sensitive to the fallout rate between the time the grain headed out and its harvest than the other foodstuffs analyzed. It is less sensitive to either the cumulative amount in the soil or the total input from fallout. As a result, large variations may occur in the same crop grown in different areas or in crops grown in a given area at different times.

The high radionuclide content of wheat was responsible for at least one minor crisis in the administration of the fallout control program. The state health commissioner of Minnesota became alarmed at reports of rapidly rising radioactivity of wheat in the state and recommended widespread withholding

TABLE 12.18. Strontium-90 Content of Wheat and Flour in the U.S.* (picocuries per kilogram)

Year of Harvest	Average from 9-15 States Weighted for Production	
	Observed	
	Wheat	Flour
1959	50	10
1960	25	5
1961	25	10
1962	85	15
1963	220	40
	Predicted	
1964	140	20
1965	80	10

* Predicted and observed values have been rounded to the nearest 5 units for purposes of comparison since this is considered more in keeping with the reliability of the estimates.

of crops from the market. When this unilateral action by a state came to a head in Washington, there were objections based on the fact that, according to federal authorities, the RPGs of the FRC were designed for long-term exposure, not for short term. The ultimate result was the "Protective Action Guides," which we will review in section VII.

d. Water

Sampling of water was begun very early in the years of nuclear weapons testing.^(a) In 1955, radioactivity measurements were added to the National Water Quality Control Network. There were about fifty sampling locations. The work has been continued under the Federal Water Pollution Control Act as a cooperative project between federal, state, and local agencies. All of the major river basins in the United States were included.

The early results (see the Congressional hearings for 1959) showed very low activities in drinking water, partly because there are few entities in good drinking water to which radioisotopes can attach themselves or travel with. The work continued, however, largely as a routine operation of the PHS.

In early 1976, the EPA produced a large report on quality criteria for water. It did not include radionuclides, and it focused as much on aquatic life and recreational use of waters as on domestic uses. However, the EPA promulgated regulations for radioactivity in drinking water in July 1976 with a planned effectiveness date of June 24, 1977. The document describing the interim drinking water regulations (EPA 1976) for many types of contaminants gives a detailed discussion and maximum contaminant levels for both alpha- and beta-particle activities (see section VII).

(a) The sampling of water for content of naturally occurring radionuclides has been described in earlier chapters (e.g., 1 and 3).

Obviously, these recommendations from EPA were not developed with fallout phenomena particularly in mind. Nevertheless, it must be remarked that some of the proposed levels are now low enough that the maximal activities from fallout seen during the 1960s might equal or exceed the new recommendations. The criteria for water quality are currently in a state of flux, but in general the suggested levels are considerably lower than those used for many years, including the years of maximal fallout from weapons testing. (More later.)

e. Special Problems in Arctic Food Chains

Partly because of plans for a possible Plowshare event in Alaska (chapter 14), and partly because of general interest in the radioactivity distributed at northern latitudes from the Soviet tests in the early 1960s, considerable work was done in the Arctic and subarctic. It turned out that the cesium body burden of many residents of Alaska, northern Canada, Finland, and the northern USSR were from ten to one hundred times above the average. Peaks reached were 11,000 pCi/kg in central Canada; 11,200 pCi/kg in Finnish reindeer herders; 25,500 pCi/kg in Murmansk, USSR; and 9,100 pCi/kg in parts of Alaska.

Further, it turned out that the high figures were primarily in Eskimos, Inari (Finland), or others who ate large amounts of caribou or reindeer meat. The caribou and reindeer contained high concentrations of cesium in their flesh because of their diet of lichens. Lichens are long-lived, live on rocks, and provide a veritable sponge for the accumulation of fallout radionuclides. As we saw in the case of wheat, cesium seems particularly prone to remain on surfaces. Also, the lichens are radioresistant so that the accumulated radioactivity did not significantly reduce their viability. Thus, the combination of more than the usual accumulation of radioactivity and a short food chain, viz., lichen-caribou-(or reindeer)-man, resulted in the highest readings seen anywhere as a result of global fallout. Indeed, the amounts were sufficient to cause concern, and remedial action was considered. Fortunately, the levels began to recede before obvious harm had been done. We will have to wait out the question of whether or not long-term effects will appear. (More in chapter 21.)

Details regarding the work on global fallout in the Arctic and subarctic can be seen in UNSCEAR (1977, table 19, p. 145), Koranda and Martin from LLL (1971), Martin and Koranda (1971), Miettinen from Finland (1969), and Troitskaya et al. (1974) from the Soviet Union. (More in chapter 15.)

f. Discrimination Factors

The work on food, both field and laboratory, turned up biological phenomena that were in some respects the obverse of the concentration factors described in earlier sections of this chapter. In systems where the radionuclide of interest has analogues, and the two were followed together, as for example strontium/calcium and cesium/potassium, it frequently happened that the radioisotope passed through various steps in the food chain less readily than the stable analogue.^(a) At nearly all steps, we find for example that strontium is less readily absorbed, less readily deposited in bone, more readily excreted, etc., than its analogue, calcium. These differences were quantitated by the introduction of entities called discrimination factors. We will review them and some possible

(a) This is not because one member of the pair was radioactive and the other stable. The same phenomena were seen with stable strontium for example.

mechanisms when we consider laboratory research in chapter 13. They can result in very real differences between the amounts of some isotopes in fallout and the amounts eventuating in the tissues of man.

g. Protective Actions

Finally, in this brief consideration of food and water, we must emphasize the fact that those concerned with the evaluation of fallout worked out many types of protective actions that might be applied if needed. Obviously, they are more pertinent to the acute contaminating event than to the slow accumulation from global fallout. Yet, they could be activated if needed, even for worldwide fallout. In terms of dietary entities, the following can be mentioned:

1. shifting of cattle and other animals to stored feed;
2. impounding of contaminated feed to allow for radioactive decay;
3. diverting perishable commodities like milk to the production of processed foods;
4. removing radionuclides from food, e.g. milk;^(a)
5. reducing uptake of radionuclides as, for example, by the administration of stable iodine to flood the thyroid and reduce the uptake of radioiodines.^(b)

Even though some states have authorized stockpiling of stable iodine for potential distribution, there is still considerable hesitation in the medical community since the procedure has its own hazards. Recently, the California Medical Association drafted a position statement (CMA 1983) that suggests limited use if it is determined that the persons involved will receive a thyroid dose from radioiodines of over 25 rad. This, like other statements of position, has not yet been promulgated officially.

In general, the reason for developing guides for protective action has been as much to prevent unwarranted application of control measures, since they could frequently cause greater harm than the quantities of radionuclides present, as to control actions once the requisite level has been reached (see section VII).

D. Work in Other Countries

The international flavor of the enterprise concerned with global fallout has been obvious as we proceeded. Nevertheless, for the record, we should pause briefly to enumerate in one place the general nature of the research done and contributions made by organizations outside of the United States. The review will perforce be very cryptic.

The contributions came from individual countries and also from multinational organizations like the United Nations (UNSCEAR), the International Atomic Energy Agency (IAEA), and the International Radiation Protection Association (IRPA).

- (a) An elaborate system was set up by both industry and government to remove strontium from milk, for example, using ion exchange techniques; see U.S. Department of Health Education and Welfare pamphlet in the *Environmental Health Series* (DHEW 1967).
- (b) The pros and cons of the procedure of using stable iodine for prophylaxis have been aired almost from the beginning of consideration of environmental contamination by radionuclides. The thrust is more toward a potential nuclear power plant accident than fallout from weapons. Nevertheless, the *raison d'être* would be the same for cases of local fallout. We will glimpse the work briefly in chapter 19, where some of the literature will be cited. It is mostly clinical, not experimental.

The laboratories in the United Kingdom and Canada were on pretty much the same track as U.S. organizations. The important documents of the Medical Research Council have been cited already (MRC 1956, 1960). The table of contents of its 1960 report and its appendices are given as note 3 at the end of this chapter to provide not only an overview of the subject matter but a list of the investigators who contributed the several appendices.

Much of the U.K. work was experimental and will be considered in chapter 13. In the field situation, there were measurements of strontium in man (Loutit 1967 and 1969); measurements of environmental contamination from nuclear weapons (Russell and Bruce 1969; Bruce and Russell 1969); risk evaluation for protection of the public (Dolphin and Marley 1969); development of radiation protection standards for environmental contamination (Morley and Bryant 1969); research on transfer of ^{90}Sr through food chains to man (Bruce, Bartlett, and Russell 1967); and much work that appeared in later symposia of the IAEA and the IRPA. There was also an international symposium on strontium (Lenihan, Loutit, and Martin 1967).

From Canada, there was early work on the magnitude of the biological hazard from ^{90}Sr (Newcombe 1957, Chalk River) and ^{90}Sr fallout levels in Canada (Booth and Samuels 1969). The latter work, from the Canadian Department of National Health and Welfare in Ottawa, showed a marked effect of soil type on the amounts of ^{90}Sr in milk. There were low values in southern Ontario as compared to Quebec and New Brunswick (grey-brown podzolic with a natural high calcium content in the former and "true" podzolic with a lower natural calcium content in the latter). Other work from Canada can be identified through the index.

Work from France, which concerned food-chain contamination, has already been cited in part (Pellerin et al. 1967). Nearly all the IAEA symposia contain work from France.

There were occasional reports on the ^{90}Sr content of human bone in many countries, much of it quite recent work, e.g., Dehos and Kistner (1980) from West Germany.

The Japanese were busy too with, in addition to the extensive survey work described in connection with the Pacific tests, early reports on strontium and cesium (Izawa, Tsubota, and Nagai 1961.); fallout ^{90}Sr in beer (Shiraishi and Ichikawa 1970); (a) plutonium content of the soil of Nagasaki (Sakanoue and Tsuji 1971), which was well above background even twenty-four years after the bomb detonation; and also plutonium in human organs (Okabayashi 1979). These are just samples.

The extent and the depth of Soviet work can only be hinted at here. The USSR workers measured at least everything measured in the U.K. and U.S. work. They found higher body contents of fission product radionuclides than in U.S. or U.K. residents, especially in the far north for reasons discussed earlier. They also appear to have devoted much more attention to protection of their population. An excellent summary of USSR work to the mid-1960s can be found in the book by Petrov et al. (1966) already cited. The table of contents of his book is shown as note 4 at the end of this chapter.

(a) It was not high enough to cause concern but showed that the contamination was entering by way of the raw materials used for making the beer.

The Soviet volume is very complete with nomograms for determining external dose from fallout, re-entry times permissible after different contaminating events, additional radiation dosage that can be allowed at various times after a single justified-risk dose, etc. It also has much detail on the doses from fission products taken internally and descriptions of applicable field instrumentation. Although considerably shorter, this volume may in some areas be more complete than the U.S. volume, *The Effects of Nuclear Weapons*, already cited.

Further citations to work done abroad as well as in U.S. laboratories can be found in a bibliography of the world's literature up to 1961 prepared for the U.S. AEC by Bost, Vorees, and Smelcer (1961).

VII. Standards For Fallout^(a)

Throughout the discussions in this chapter, we have indicated how the amounts of radionuclides found in the biosphere, including humans, might be related to certain criteria of possible effectiveness. These criteria were developed, sometimes directly sometimes rather complexly, from recommendations of bodies such as the NCRP, the International Commission on Radiological Protection (ICRP), the IAEA, the National Academy of Sciences, and via regulations developed by various federal and state authorities, including for the test sites, the military (Hacker undated). Much computational research went into these efforts, although not much laboratory research could be brought to bear except for metabolic cycles, transfer coefficients, and the like. A large segment of the biomedical community was involved, in one way or another.

A general though brief discussion of the cognizant organizations and the general processes of setting standards for exposure to radionuclides is given in chapter 16. There were, nevertheless, facets peculiar to environmental contamination that are better discussed here as part of these chapters on environmental aspects of radionuclide releases. They apply, of course, as much to contamination from general nuclear activities, including nuclear reactors, as to fallout from nuclear weapons tests, but since they grew largely around the problems of local, regional, and global fallout, they are appropriately discussed here.

(a) Note added in proof: In July 1986, S. C. Black and G. D. Potter at the EPA Laboratory in Las Vegas published a historical perspective of selected health and safety aspects of nuclear weapons testing (*Health Physics* 51:17-33). This is a compact, authoritative, and carefully researched summary of much of the material reviewed in this chapter, particularly that pertinent to standards and offsite exposures. It provides updates to some of the sections and adds specific references to AEC and PHS reports that were either not available or not known to this author at the time of writing. These include AEC reports on the continental tests, very specific information on exposure standards for NTS, and work of the PHS in measuring iodine burdens in people following an event labeled "Palanquin" (a Plowshare event) and one labeled "Pin Stripe." There is much more discussion of the role of instrument development in developing and applying standards for fallout than was possible in this chapter. The author's point, consistent with the thrust of this chapter, to "serious over-sight affecting human exposure, namely, that of not recognizing the relative information of all potential transport/dosimetric pathways for risk assessment." Yet, the picture drawn is primarily one of conscientious application of the knowledge then available.

A. Early Activities

The several organizations concerned with testing could not wait for development and promulgation of formal special standards. Ad hoc levels were chosen for activities such as "Operation Crossroads" and those at NTS in the early 1950s. The standards for radiation protection set by the AEC for the 1953 series at NTS as developed by a special committee were as follows:

1. The external dose to non-participating inhabitants of radiation from gamma rays shall not exceed the accepted international permissible dose level of 300 mR/week, which may be integrated over a maximum of ten weeks.*
2. At a point of human habitation, the activity of radioactive particles in the atmosphere, averaged over a period of 24 hours, shall be limited to 100 microcuries per cubic meter of air (corresponding approximately to a ground level gamma intensity of 30 mR per hour).
3. The 24-hour average radioactivity per cubic meter of air, due to suspended particles having diameters in the range of 0 microns to 5.0 microns, shall not exceed 1/100th of the above; nor is it desirable that any individual particle in this size range have an activity greater than 10^{-2} microcuries calculated 4 hours after the blast.

*Subsequently modified to allow integration over the duration of the test series which in 1953 was 13 weeks or 3.9 R.
(Johnson and Carter 1984, p. 1270).

It will be noted that only gross activity from radionuclides was stated—partly because the instrumentation could not distinguish among isotopes except crudely. The resemblance of these to NCRP and ICRP recommendations and the Code of Federal Regulations for occupational exposure is more than fortuitous.

Some of the individual laboratories felt a need to devise criteria for specific radionuclides in the environment, much as they had done in the MED for occupational exposure. A general effort aimed at maximum allowable concentrations of fission products in the air was carried out by the Radiological Division of the U.S. Army Chemical Corps (Harvey 1952).

During the 1957 U.S. Congressional hearings, there were many discussions that involved, either formally or informally, questions of standards for exposure of the population to fallout (see, for example, Dunning 1957b). These took two forms: (1) what levels were permissible, and (2) discussions of how long testing could continue at the then-current rate or even how much the rate could be increased before the amounts of fallout radionuclides in the biosphere and in humans would reach unacceptable levels. We will address the permissible levels and their evaluation first.

In earlier sections, we described the Sunshine Unit as $1 \mu\text{Ci } ^{90}\text{Sr/gCa}$ and the occupational limit then accepted as $1,000 \mu\text{Ci/gCa}$. Also, we saw that those concerned with the Sunshine Project suggested a population dose of one-tenth of the occupational,^(a) or $100 \mu\text{Ci/gCa}$ (100 Sunshine Units). This idea had a certain amount of informal backing in organizations like the NCRP, but neither the NCRP nor any of the other recommending bodies issued a formal declaration of policy on population exposures at this early time. The early report of the National Academy indicated disagreement among the committee members. As quoted by Brues at the 1959 hearings (p. 1321), the report indicated:

(a) The philosophy of this relation and others is discussed in chapter 16.

First responses to the question (i.e., permissible dosage to large populations) ranged all the way from the permissible industrial level down to no radiation at all. . . . The uncertainty . . . stems from our ignorance as to whether or not there is a true threshold for such late effects as malignant tumors and the degree of variation in response of equally exposed individuals.

This was before the radiation protection fraternity had decided that "for prudence" a linear no-threshold response should be assumed to hold. The question of the presence or absence of a threshold permeated all of the discussions in those days.

Furthermore, people quite understandably got hung up on the numbers. Assuming linearity, the radiation from fallout could be calculated to produce two extra cases of leukemia in the combined populations of Baltimore and Washington, i.e., 202 per year instead of 200, in a population of three million; 100 extra cases per year in Japan, i.e., 10,100 instead of 10,000 in a population of one hundred million; or 1,500 extra deaths from leukemia per year in the world population. Since both leukemia and bone cancer were assumed to be produced by the deposition of ^{90}Sr , it was easier to lump the statistics for both in estimating long-term effects. On this basis, and assuming a linear no-threshold dose-response relationship, a total of 50,000 total cases was calculated as attributable to fallout over a thirty-year period in the world population (Selove, in U.S. Congress 1957, p. 1292). It was also calculated that 12,000 extra deaths from leukemia and bone cancer would potentially occur in the U.S. population over the thirty-year period (U.S. Congress 1957, p. 1296). Like all such calculations, these show the effect of multiplying even a quite low incidence rate by a very large population.

We are still struggling with this problem of the numbers not only for radiation-induced changes but any other effects whose dose-response curve is assumed to be linear with no threshold. The percentages may seem minuscule until the numbers are multiplied by the population of the world. We will always face this dilemma, especially in the balancing of risks and benefits. Yet, only by such balancing will we attain solutions.

Another factor that entered the early deliberations on standards for fallout was the "worry level." It is now common practice to report, even require action, at levels only a fraction of the ones chosen as "permissible" and to have all operations at levels as low as reasonably achievable (ALARA). William F. Neuman in his testimony at the same hearings (p. 1319) expressed the view that the British report (MRC 1956) had adopted a figure of 10 Sunshine Units as a "worry dose" at which the rate of testing and other factors should be re-examined carefully before the inexorable climb of radionuclide content of the body progressed beyond the permissible level.^(a) The general idea of a worry dose received support from others, e.g., Langham at the same hearings and in other discussions.

(a) The statement in the MRC report is ". . . we believe that immediate consideration would be required if the concentration of radioactive strontium in bone showed signs of rising greatly beyond that corresponding to one hundredth of the maximum permissible occupational level." Since the occupational level was 1,000 Sunshine Units, the "worry level" became 10 S.U. The 1960 NAS-NRC report does not use quite the same terminology and puts the "warning level" at one one-hundredth of the occupational and one-tenth of the population level.

These considerations were not limited, of course, to strontium. Levels were similarly set for other important radionuclides. The processes were similar for all, except that the bone seekers were related to radium, the soft-tissue seekers to the permissible doses for external low-LET radiation.

The second facet of the discussions, i.e., how long and at what rate could testing continue before the MPC was reached or exceeded, brought in the results of laboratory as well as field research. First there had to be good data for the rate of fallout, its accumulation with time, the inventory still to come, and the passage from soil or air to the tissues of humans. We have already seen examples of how most of these entities were estimated. For the final step, we can turn again to the 1957 hearings. An example is given below.

Neuman was unhappy with using ^{90}Sr as produced in the past for predictions because "these data are inextricably bound to past conditions, testing rates, types of weapons exploded, and so forth." Instead he developed a model using measured behavior of *natural* strontium compared to *natural* calcium to see to what degree strontium was a "counterfeit" for calcium. As we saw earlier, it was not an exact match. His model proposed that the strontium/calcium ratio in passing through each organ or process in the chain from ingestion to deposition in human fetus or mother's milk or cow's milk was reduced by one-half. With four major processes—gut absorption, urinary excretion, blood to placenta or mammary gland, and placenta to fetus or to milk—the overall change in ratio or the overall discrimination factor was eight.

To go further, it was assumed that at equilibrium the amount of ^{90}Sr that can be produced will be equal to that which decays in any given year, or 2.5% per year due to the relatively long half-life of ^{90}Sr . The rest follows. Introducing the discrimination factor and corrections for stratospheric hold-up time, the non-uniformity of fallout, and the nonuniformity of population intake and response, it was possible to calculate a tolerable ground-level concentration, and from it a maximum test rate (see p. 715 of the cited hearings for details).

Thus, using an MPC in bone and figures for the amounts of ^{90}Sr produced per megaton of fission, a limiting testing rate could be calculated. Using an MPC of 100 Sunshine Units, the limiting equilibrium test rate came out as 4.4 MT equivalent of fission products injected into the stratosphere annually. Using an MPC of 50 Sunshine Units, the limiting rate was, of course, 2.2 MT equivalent per year.

Other calculations were made using somewhat different quantities for the parameters and radiostrontium rather than natural strontium. Yet, the eventuating equilibrium rates were not widely different considering the many assumptions and uncertainties involved.^(a)

At the time of these early hearings, 2.2 or even 4.4 MT of fission per year seemed safely ahead of the actual testing rate. Indeed, some of those interested pointed out that it would take decades just to reach the equilibrium value! This soon changed with the marked increase in megaton equivalents associated with hydrogen bomb tests. The temporary test ban near the end of the decade of the fifties was welcomed by all biologists as one way to check out these myriad calculations before processes of serious biological harm could be unwittingly initiated.

(a) Perhaps this figure for maximum allowable concentration was firmer than many of the others, for it was based on the well-established MPC of ^{226}Ra in bone and the toxicity of strontium relative to it determined directly in animal experiments.

B. Establishment of Population Exposure Standards

The above standards closely resemble those for occupational exposure. There is little doubt that the exigencies of the fallout problem, along with the possibilities for environmental contamination from sources such as nuclear reactors, stimulated the recommending bodies to work in some depth on the formulation of limits for population exposure. The influx of information on genetic effects would have seen to this if nothing else had done so. The AEC's standards as promulgated in the Code of Federal Regulations included figures for population exposure for all isotopes (table II of Appendix B of Code 10 CFR 20 1972). However, except for iodine, a case we have already discussed, they were simply scaled down from the occupational levels by a factor of ten.

Publication 7 of the ICRP (ICRP 1965a) introduced the concepts of critical nuclides, critical exposure pathways, and critical population groups. In each case, these represented the entity most likely to give or to receive the highest dose or to involve the greatest hazard (more in later chapters). This greatly simplified the setting of standards for the public around sites of environmental contamination and provided many economies in the conduct of environmental monitoring. These concepts have continued in use over the decades since.

A very helpful analysis of how dose limits for members of the public differ from dose limits for occupational exposure is given by Sowby (1969) from the United Kingdom. He points out the very real problems of actually checking the magnitude of the dose received by individuals in the population.

Publication 9 of the ICRP (1965b) expanded on the exposure of populations, especially the genetic dose limit. As we will see in chapter 16, there was a period when not only the ICRP but the American counterparts such as NCRP and the National Academy, and also the United Nations Scientific Committee issued separate limits for genetic and for somatic effects. However, the genetic limit was couched in terms that permitted more planning for avoidance than for assessment or remedial action. The general levels for population exposure were still about one-tenth of the occupational.

By far the most comprehensive approach to population standards during the years of most concern about fallout was that of the FRC. (For its organization and development, see chapter 16.) In its first report (FRC 1960), it introduced the term "Radiation Protection Guide" to emphasize the philosophy that there can be no single permissible or acceptable level of exposure without regard for the reasons for permitting the exposure. It suggested population exposure guides of 0.5 rem per year to the whole body for the individual (i.e., one-tenth of the normal occupational guide) and 5 rem in thirty years to the gonads for the population average. The latter was based on potential genetic changes. It was identical to the 0.17 rem per year developed from the assumption that the average dose to even a small population group should be lower than that allowed an individual. A factor of three potential difference in sensitivity was assumed, and the figure thus became $0.5/3$ or 0.17 rem/year. The genetic dose was theoretically to be applied to relatively large population groups. It would thus be particularly applicable to global fallout and isotopes like ^{14}C that might deliver a genetically significant dose.

The second FRC report (FRC 1961) introduced the idea of ranges for the RPG for both occupational and population exposure. Range I encompassed intakes that would not be expected to result in any appreciable number of individuals in a population reaching a "large fraction" of the RPG. Range II represented

intakes that would be expected to result in average exposures to population groups that might approach but not exceed the RPG. Range III represented intakes that would be expected to result in exposures exceeding the RPG. Recommended degrees of control ranged from routine surveillance through active surveillance to consideration of positive control measures for the three ranges, respectively.

Each radionuclide of high importance to fallout problems was examined in detail, and figures were derived specifically for that isotope; quite a different procedure from the simple application of a scaling factor. The report also discussed concentration values related to the applicable RPGs but warned against indiscriminate application without due regard to the environmental medium contributing the intake, i.e., food, water, air, or combinations thereof.

The figures given in the second report are:

	¹³¹ I	⁸⁹ Sr
Range I.	0-10 $\mu\text{Ci/day}$	0-200 $\mu\text{Ci/day}$
Range II.	10-100 $\mu\text{Ci/day}$	200-2,000 $\mu\text{Ci/day}$
Range III.	100-1000 $\mu\text{Ci/day}$	2,000-20,000 $\mu\text{Ci/day}$
	⁹⁰ Sr	²²⁶ Ra ^(a)
Range I.	0-20 $\mu\text{Ci/day}$	0-2 $\mu\text{g}/\text{day}$
Range II.	20-200 $\mu\text{Ci/day}$	2-20 $\mu\text{g}/\text{day}$
Range III.	200-2,000 $\mu\text{Ci/day}$	20-200 $\mu\text{g}/\text{day}$

It will be noted that Range II is about equivalent to the 10 CFR 20, NCRP, and ICRP numbers, but is not necessarily a factor of ten below the occupational limit in each case, particularly since it is a range.

These numbers were, of course, not available yet at the time of some of the most intensive discussions of limits for fallout described in the previous section. They were, however, available for the deliberations of the 1960s.

Although the figures for the RPGs for population exposure were useful guides, they assumed long-term intakes. As described in the previous section, application of the RPGs to short-term exposures, such as an acute contaminating incident or the passage of a fallout cloud, was frowned upon in official circles. Yet, those responsible for any needed action complained that they had no guidance other than that for long-term exposure. This stimulated the FRC to devise a new set of guides called "Protective Action Guides," which were developed in reports number 5 and 7 (FRC 1964a, 1965).^(b) There were special advisory panels on environmental factors and dosimetry and a special report from an advisory committee of the National Academy of Sciences-National Research Council (NAS-NRC 1964) on the implications to man of irradiation by internally deposited ⁸⁹Sr, ⁹⁰Sr, and ¹³⁷Cs. The composition of the FRC, the NAS-NRC advisory committee, and the ad hoc panels are given as note 5 at the end of this chapter.

A Protective Action Guide (PAG) is the *projected* absorbed dose to *individuals in the general population* that warrants protective action following a contaminating event. The FRC considered both the acute localized contaminating event and worldwide contamination from stratospheric fallout. They considered

(a) Not of interest to situations involving fallout from weapons tests.

(b) Reports number 2, 3, and 4 concerned estimation and evaluation of fallout but not radiation protection standards (FRC 1961, 1962, 1963).

isotopes in three categories: I.—transmission limited to the pasture-cow-milk-man pathway, II.—transmission through other dietary pathways, and III.—long-term transmission through soils to plants in the years following a contaminating event.

The PAGs developed by the FRC can be summarized as follows:

Iodine-131 and the thyroid—a projected dose of 30 rad to the thyroid of individuals in the general population. It is assumed that this condition will be countered effectively if the average projected dose to a suitable sample of the population does not exceed 10 rad (FRC 1964a). A table is given for calculating thyroid dose from different estimated intakes. Since ¹³¹I has short radiological and biological half-times, these recommendations have significance only for the relatively acute contaminating event.

Strontium-89, strontium-90, and cesium-137—for a category-I transmission, a mean dose of 10 rad in the first year to the bone marrow or whole body of individuals in the general population, provided that the total dose does not exceed 15 rad.

For category-II pathways, a mean dose of 5 rad in the first year to the bone marrow or whole body of individuals in the general population.

Operationally, it was suggested that the PAG would be met effectively if the average dose to a suitable sample of the population is maintained at or below one-third the PAG, i.e., 3 rad for category I and 2 rad for category II.

No PAG was recommended for category III.

Worldwide Contamination from Stratospheric Fallout—The FRC did not recommend PAGs for this situation. Their reasoning follows:

Reduction in transmission of radionuclides to man under worldwide fallout conditions could only be achieved by long-term changes in (1) agricultural practices, (2) food processing practices, or (3) basic dietary habits. Consideration of such basic economic and social changes is not warranted when annual doses from environmental contamination are comparable to the numerical value of the annual dose recommended for the RGC. It has not been possible to visualize circumstances in which the balancing of the risk of radiation against the undesirable consequences of the protective measures on social, economic, and political institutions can be reduced in advance to numerical guides for mandatory action under these circumstances.

On the basis of this information on stratospheric fallout the Council concluded that the health risk from radioactivity in food over the next several years would be too small to justify protective actions to limit the intake of radionuclides either by diet modifications or by altering the normal distribution and use of food, particularly milk and dairy products.

In view of these considerations it is recommended that:

Surveillance of the radionuclide content in food products contaminated with worldwide fallout be continued at levels appropriate to the situation.

Surveillance and research programs examining the special ecological situations in the arctic region continue until future trends can be predicted with greater confidence.

Nationwide programs to reduce potential exposure of the population from gradually increasing levels of environmental contamination, such as that associated with worldwide fallout, are not necessary now nor for future levels of fallout from past testing. (Quoted with slight organizational modifications from FRC 1965.)

The promulgation of the PAGs caused both resentment and misunderstanding in parts of the biomedical community. It was argued that "radiation is radiation," and it should not matter whether the source was fallout, a nuclear installation,

or any other. However, after some careful explaining, the point was accepted, viz., it was not so much the source as the time course of the exposure that made the difference.

Quite clearly, the FRC's actions were more helpful quantitatively to evaluation of local fallout and events such as those around the test sites than to global fallout.

The setting of exposure standards for the population has not ceased in the intervening years, but it has, of course, changed in emphasis away from fallout problems per se.

In its 1971 basic radiation protection criteria report, the NCRP set dose limits for the public or occasionally exposed individuals at 0.5 rem in any one year and population dose limits at 0.17 rem average per year for either genetic or somatic effects (NCRP 1971). The NCRP did not develop population dose limits for individual radionuclides. The AEC and its successor for regulation, the Nuclear Regulatory Commission, stuck assiduously to the limits for radionuclides shown in Appendix B table II of the Code of Federal Regulations, Part 20, except for the modifications in Appendix I already described. This may change in the near future. (P.S., still waiting in 1987.)

In 1979, the ICRP adopted a report on the assessment of doses to man from radionuclide releases into the environment (ICRP 1979). This considered both planned and unplanned releases and is full of modeling for dose predictions and the use of dose predictions in decision making. The report is essentially a supplement to and expansion of Publication 7 already cited. Dose commitment in the sense first used by UNSCEAR to apply to the consequences of fallout was applied generously. The modeling utilizes two quite different methods, the concentration factor method and the systems analysis method. Since no new numerical guidance is introduced in this report, we will not discuss it further now except to recommend it to the reader interested in examining current philosophy and methodology. It is understood that the ICRP is now working on a comprehensive analysis of population exposure standards.

In the United States, the FDA Administration prepared guidance concerning radioactive contamination of human food and animal feeds (*Federal Register* 1978). This guidance proposed a "preventive" PAG applicable to situations where the protective actions would cause minimal impact on the food supply and an "emergency" PAG applicable to situations where the actions could have considerable impact on the food supply but were justified by the magnitude of the projected health hazards. The levels proposed were:

Preventive Guides(a)	¹³¹ I		¹³⁷ Cs		⁹⁰ Sr		⁸⁹ Sr	
Initial Deposition (μCi/m²)	0.14		1.7		0.34		6	
Total Intake (μCi)	0.09		7		0.2		2.6	
Emergency Guides	Infant/Adult ¹³¹ I		Infant/Adult ¹³⁷ Cs		Infant/Adult ⁹⁰ Sr		Infant/Adult ⁸⁹ Sr	
Initial Deposition (μCi/m²)	1.4	18	17	65	3.4	25	60	3,000
Total Intake (μCi)	0.9	10	70	110	2	12	26	1,000

(a) Infant as critical segment of the population.

These guides were derived from and are closely related to those prepared fourteen years earlier by the FRC and were planned as replacements for them.

Doses associated with these, including addition of a new category of "Alert," are given below (NRC 1977):

PAG	Alert (Average Dose)	Preventive (Dose Commitment)	Emergency (Dose Commitment)
Thyroid	50 mrem/yr	3,000 mrem	30,000 mrem
Bone Marrow or Whole Body	17 mrem/yr	1,000 mrem	10,000 mrem

The resemblance of these figures to others we have been considering are not immediately obvious. The supporting documentation presents the arguments and derivations.

The recommendations of the Bureau of Radiological Health (BRH) were considered not sufficiently conservative by some, e.g., Swick and Morgan (1980). Shleien of BRH responded to the criticisms by pointing out that the PAG was a *projected* dose commitment rather than one that is actually reached and also that certain numbers had not been quoted or used correctly (Shleien 1981a). There is now a fairly consistent cadre of individuals who feel that all of the present standards for population exposure are too high, with the possible exception of the new EPA guidelines that are very low indeed. The current status of these proposals from FDA is not known to this author.

Recently, the CRC Press has developed a *Handbook of Environmental Radiation*. A chapter in it by Denham and Waite (1982) considers "Action Guides and Countermeasures." Considerable space is devoted to Emergency Defense Levels for many radionuclides important in fallout. Also, it summarizes international codes and criteria for the transuranic elements. The data are assembled from sources quoted earlier in this chapter and in chapters 11 and 16.

The new EPA guidelines are still in preparation except for a few radioactive substances. We should mention that, in addition to the guidelines being prepared for environmental components, especially water, the EPA developed in the mid-1970s an entity known as "Environmental Dose Commitment," which was aimed more at contamination from nuclear reactors than from fallout. It was an extension and refinement of the average dose commitment developed in the 1969 UNSCEAR report largely around the problems of fallout. While the UNSCEAR formulation was based on an infinite time integral of the average dose rate in a population, the EPA took into account expected changes in population size and computed a collective dose rather than an average dose. The EPA viewed their method as supplying a better assessment of the total impact of, for example, the nuclear power industry. These matters are discussed by Richardson (1975), who quotes a very similar projection system developed by Beninson (1974).

VIII. Dilemmas, Problems, and Progress

A. General Comment

There can be no doubt in the mind of anyone reading this chapter that fallout from nuclear weapons tests brought a shower of dilemmas and problems upon the scientific community and society in general. Most of the dilemmas and

many of the problems were as much political and moral as scientific and technical. It is not appropriate here to expound in any detail on the former. Yet, in some instances scientific and technical aspects were so intimately intertwined with the political and moral questions that they require comment, even here.

1. Should We Have tested?

A persistent dilemma for the biosociopolitical community and for society in general has been this one. In a sense, the question was not so much a dilemma for individual decision makers as a collective dilemma with the weapons designers and those responsible for national security on one side and much of the biomedical community on the other. The second volume of the history of the AEC by Hewlett and Duncan (1969) gives the picture of the milieu in which the AEC had to work in the period 1947 to 1952. A more personal account is contained in the autobiography written by Lewis Strauss, chairman of the AEC during many of the critical years of weapons testing. The book is entitled *Men and Decisions* (Strauss 1962).^(a) Chapter XIX, "Nuclear Tests, Fall-out, and World Opinion" concentrates on the testing dilemma as seen by one who had to make decisions on both sides. Strauss begins his chapter as follows:

This is a chapter about a subject which many people find repulsive. It offends reason to think that, at this point in human development, experience should not be overwhelmingly convincing that war is the most witless of human enterprises. It is a fact of life, however, that experience frequently fails to convince.
(Strauss 1962, p. 404)

After considerable exposition of the AEC's involvement with nuclear weapons development, interaction with the military, and some description of the Pacific tests and the numerous reports on all aspects, including biological effects, Strauss epitomizes the position of the AEC regarding the Pacific thermonuclear tests as follows:

As soon as the scores of scientific reports had been submitted and studied, a comprehensive report was issued the following February under the caption "A Report on the Effects of High Yield Nuclear Explosions." In an introduction, attention was called to the fact that "If we had not conducted the full-scale thermonuclear tests in question, we would have been in ignorance of the extent of the effects of radioactive fall-out and, therefore, we would have been much more vulnerable to the dangers from fall-out in the event an enemy should resort to radiological warfare against us. . . ." Also, "In the event of war involving the use of atomic weapons, the fall-out from large nuclear bombs exploded on or near the surface of the earth would create serious hazards to civilian populations in large areas outside the target zones. The Atomic Energy Commission hopes that these dangers will never be experienced by mankind. However, until the possibility of an atomic attack against us is eliminated by a workable international plan for general disarmament, the study and evaluation of the effects of weapons which might be used against us and the improvement of our means of self-defense are a paramount duty of our government."
(Strauss 1962, p. 412)

(a) The author is indebted to Dr. H. David Bruner, Bonita Springs, Florida, formerly of the AEC, ERDA, and DOE staff for providing me with a copy of this book and much other pertinent literature.

Biomedical problems receive increased emphasis on each succeeding page, but Strauss returns to his original theme near the end of the chapter, "the real danger to the human race is not the continuance of weapons tests. The real danger is nuclear war" (Strauss 1962, p. 424).

Given those alternatives, the biomedical community saw no dilemma either. What seemed to be hardest for the biomedical community to get across was its concern for the large gaps in our biological knowledge. The admonition to hold back as much as possible while ongoing research on the long-term effects of fallout, indeed of ionizing radiation from any source at low levels, could gather the critically needed new data did not mean that the biomedical community was against national security. However, there was reason for emphasis on keeping the testing rate low and for the strong presentations to the military to do the least possible testing and finally to move all testing underground.

The long-term experiments at Argonne, Davis, Hanford, Los Alamos, Lovelace, Rochester, and Utah, etc., were started partly, though not exclusively, to approach these questions. It is a commentary on the time needed to do thorough biological work on large animals that many of these experiments are just now coming to satisfactorily documented conclusions—ones that can help support estimates of risk. The earlier scientific dilemma would have been less acute had we had these firm data, but we are not home free even now.

2. Risk Versus Benefit

As noted earlier, and to be emphasized in later chapters, the view grew during the years of the fallout controversy, though not exclusively because of it, that the radiation dose-response relationship had to be regarded as linear with no threshold. Thus it followed that any extra radiation produced extra risk. The corollary was that there should be no radiation exposure unless there was a concomitant benefit. The review in this chapter should make it clear that fallout confers no direct health benefits. Any benefits had to be in other quarters.

The weapons-testing situation did not facilitate specific descriptions of benefits. The generalization that national security required weapons testing was vague indeed compared to the reasonably obvious benefit of an x ray for diagnosis. Furthermore, in the early days, the biological risk could not be spelled out with any precision. We thus had two relative unknowns—the details of benefits to the nation's security from improved weapons design and the details of the biological risk. The former were locked up by classification (they might not have been understood anyway); the latter were in dire need of quantification. No wonder there was agitation and controversy!

Much has been said about the withholding of important information during the testing years. This clouded the balance of risks and benefits. This author is in no position to comment except to state that in over one hundred interviews in preparation for this book (see Appendix A), lack of knowledge was decried much more than withholding of knowledge beyond the needs of national security. It was the public relations aspects of the operation that drew the most criticism.

In contemplating the two aspects of the dilemma of testing, one wonders if there was ever or ever could be any one individual, even the President of the United States, even the chairman of the AEC, who was fully cognizant of both sides of the equation, i.e., a person who knew in *equal depth* both the true value of the information obtained from testing and the true dimensions, small or large, of the biological risks being countenanced. It seems most unlikely. The

result was a need for consultation and weighing of the evidence given by experts with very disparate backgrounds. And behind it all was the fact that we did not know the answers to the biological questions. We still do not, although we have made much headway. Before we indulge in unbridled criticism of our fellow citizens, we should remember that our largest problem was and is, ignorance. Nature gives up her secrets with great reluctance.

B. Hidden Doses

At several points in this chapter, we have pointed out that the second part of the dose from fallout, the possible long-term effects from ingestion or inhalation of radionuclides in contrast to the external radiation dose, had been either neglected or measured rather superficially. This was true even for possible short-term effects, except for Operation Crossroads, the Marshallese, and some other events in the Pacific. It took the iodine scare to bring the possible role of food-chain contamination or direct contamination of humans from radionuclides of continental or global origin into proper focus. We also pointed out the accepted maxim at the test sites that maintenance of the external dose below limits would automatically protect against internal dose from inhalation or ingestion. We know this was correct only for close-in, relatively fresh fallout and even then not fully correct. It was less correct still for longer-term exposure via environmental contamination. Because of these facts, we could say that there was something missing from the accounts, and that this may have contributed in some degree to the ultimate risk.

John Gofman, whose work and opinions we have met in other chapters and whose treatise on low-level radiation effects we have already cited (Gofman 1981),^(a) attached the colorful term "hidden dose" to these phenomena. He cited specifically (1) additional internal dose possibly received by the men involved in the "Smoky" and related incidents, (2) a possible contribution of a dose from fallout to the dose-response relationships and the dosimetry of the Japanese at Hiroshima and Nagasaki, and (3) unexplained incidence of leukemia in individuals who entered Nagasaki soon after the bombing.

The first instance is essentially identical to what we described in section V, except that Gofman applied the reasoning to the analysis of Caldwell, Kelley, and Heath (1980) and quantitated the "hidden dose" by comparison of the leukemia incidence in the "Smoky" cohorts to that in the Hiroshima-Nagasaki survivors. The rate was much higher for the men at "Smoky." Either there was some additional dose that was not counted, or the two groups responded to grossly different extents on a per-rem basis. The former is a more logical explanation.

Despite the obvious importance of the "hidden dose," Gofman does not try to use the incidence figures for the soldiers for any of his predictive calculations "since the true dose received by these soldiers is unknown" (Gofman 1981, p. 684).

The second use that Gofman makes of "hidden dose" concerns entirely external radiation and has, therefore, not been mentioned before in these pages. Since the dosimetry for the Japanese is now in a state of flux, we must await further analysis. An important point is the finding of increased chromosome

(a) The book is largely a computational approach to the problems of radiation standards and basic radiobiology at low doses but provides also many unique descriptions of events and situations.

aberrations in individuals well beyond the range of the prompt external radiation. Was there a fallout cloud that went undetected? Gofman postulates that there was and that there were higher doses in the area. Japanese investigators Sasaki and Miyata (1968) found persistent chromosome aberrations in individuals checked out as having been beyond 2.4 km from the hypocenter yet close enough to have been in a fallout cloud if there had been one.^(a) This postulate has many implications for all of the low-dose regions of the Japanese dosimetry, in this case, an increment of external dose contributed by the possible fallout cloud.

At the beginning of this chapter, we indicated that no published measurements were available for fallout from Hiroshima-Nagasaki except for some soil-sample data near Nagasaki (Nishiyama district) taken long after the event and the finding still more recently of residual plutonium near Nagasaki. There is no way we can go back and reconstruct fallout maps as was possible around NTS. The only evidence we have is the biological indicator, chromosome aberrations, and the residual fallout in soil from that same Nishiyama district of Nagasaki (Okajima et al. 1978).

The third way in which Gofman utilizes the possible role of a "hidden dose" is based upon work by Sztanyik (1978), which he quotes. This concerns unexplained radiation effects in early entrants to that same Nishiyama district of Nagasaki. This district was protected by a hill from the direct radiation and blast effects, but did receive fallout described as "black rain" by Sztanyik. Any extra dose received by these early entrants cannot be quantified since no measurements could be made; yet, it may represent another instance where a "hidden dose" contributed to effects or complicated reconstruction of dosimetry from the instantaneous gamma and neutron fluxes.

Much of the evidence for a "hidden dose" is circumstantial. Yet, the efforts now under way to reconstruct the events of the years of atmospheric testing, particularly at NTS, will perforce have to take such factors into account. The effect may be small in many cases, but it cannot be dismissed.

C. Infant Mortality and Other Correlations

1. The Proposition

Professor Ernest Sternglass, a radiological physicist in the Department of Radiology at the University of Pittsburgh, entered the fallout arena indirectly in 1963, directly in 1968. At the 1963 Congressional hearings on fallout (pp. 410-417), Sternglass discussed the problems of the dose-response curve for low levels of ionizing radiation. He presented an analysis of data from the literature by MacMahon, the Harvard epidemiologist, and Alice Stewart and colleagues from the United Kingdom relating the number of intrauterine x rays taken during prenatal development to the incidence of leukemia in the children so irradiated. He concluded that effects appeared at doses of a few tens of millirad. As a spokesman for the Pittsburgh Chapter of the Federation of American Scientists, Sternglass pointed to the known greater sensitivity of the human embryo compared to the adult as a cause for concern about the doses from fallout radiation, including radionuclides taken internally (U.S. Congress 1963, p. 410).

(a) A generally long persistence of chromosome aberrations in the exposed Japanese had been established.

There was also a paper on the x-ray story in *Science* (Sternglass 1963) that reviewed the retrospective epidemiology studies of Stewart and of MacMahon.

There was nothing new about this qualitatively. The high sensitivity of the developing embryo and the production of gross physical or mental defects in both the irradiated individual and in future generations had been much studied by radiobiologists using animal data and was understood by clinicians. The probable doses for such effects were moderately well known, or so it was thought. It was the extremely low level of dose-effectiveness Sternglass proposed that was different. This conclusion was analyzed by many investigators, including those whose data Sternglass had used. The evidence for effects at such very low levels of x-irradiation was considered insufficient. The criticisms were sharp and perhaps made Sternglass wary of the traditional routes for scientific publication, for he turned away from them for much of his future work.

In the next years, Sternglass evidently spent much time with the help of graduate students and associates analyzing epidemiologic data of all kinds. In 1968, he entered the fallout controversy "in spades" with a series of presentations at scientific meetings, discussions, and presentations to the media and papers in periodicals such as the *Bulletin of the Atomic Scientists*, and the *Medical Tribune*. He essentially abandoned his work in radiological physics and began a crusade that varied in detail but continues to this day with the same basic tenets. This was temporal correlation of the two variables, infant mortality or leukemia incidence and low-level radiation. It began with fallout from weapons tests:

Infant mortality in the United States and much of the western world had been falling steadily since at least 1935. However, beginning at about the time of the first weapons tests, the rate of decline in infant mortality became less marked in nonwhite U.S. citizens. The same effect was seen a few years later in the total U.S. population and still later in the population of Sweden. The decline appeared to resume its old trend soon after the test ban of 1962. The typical picture as drawn by Sternglass is shown in figure 12.27. The change in slope of the mortality line was termed "excess mortality" by Sternglass and attributed by him without any question to the tests.

FIGURE 12.27. Fetal death rate for Missouri showing the "excess" over the expected rate based on the 1935-1950 regression line. Data from U.S. Vital Statistics. (Redrawn from Tomkins and Brown 1969, Sternglass's presentations.)

At the 1968 meeting of the Health Physics Society held in Denver, Sternglass presented specifics relating the fallout incident in Troy-Schenectady, New York to increased infant mortality. At the Hanford biology symposium in 1969, he showed data for excess numbers of cases of leukemia and of infant mortality on

a state-by-state basis, e.g., California, Missouri, and New York and later by cities, e.g., St. Louis, other cities to the east of the Trinity Site, etc.

At the 1969 meeting of the Health Physics Society held in Pittsburgh, Sternglass proposed correlations between levels of ^{90}Sr in milk and excess infant mortality. He proposed also that the ^{90}Sr was depositing in gonads and was responsible for genetic changes that could greatly reduce the numbers of children born in subsequent generations and increase the numbers of genetic defects.

The correlations always worked out in favor of the projected participation of fallout at the most logical time. For example, as detailed in figure 12.28, the change in fetal death rate was shown as beginning in New York State in tune with the Nevada tests, but did not appear in California until the large Pacific Proving Ground tests had generated fallout that could reach California in requisite quantity.

FIGURE 12.28. Fetal death rate reported per 1,000 live births versus time for New York State and California, before and after the onset of nuclear weapons tests in 1951. Symbols indicate the standard deviation due to statistical fluctuations alone. (Redrawn from Tomkins and Brown 1969 from presentations of Sternglass.)

As indicated, the early phases of Sternglass's crusade were largely through presentations at national scientific meetings. These were published as abstracts, but not as complete papers in the refereed journals. There were two papers in the *Bulletin of the Atomic Scientists* (Sternglass 1969c,d), two in the *Medical Tribune* (Sternglass 1969a,b), and an impassioned plea against the antiballistic missile (ABM) program that appeared in *Esquire* magazine (Sternglass 1969e).^(a)

The PHS in a sense assumed the burden of publication for Sternglass by presenting many of his original figures and arguments in an evaluation prepared by Tomkins and Brown (1969). The evaluation was done in response to the understandably intense reaction that the views propounded had in the biomedical community.

2. Critiques

Like all correlations based upon temporal associations, the scientific community wished to check out cause and effect as well as the facts themselves.

(a) The nature of the subjects addressed can be appreciated from the titles of these presentations and publications (see references). They included the prediction that no children would be born on this earth ever again if the ABM system were put in place and used. This was based upon the fact that the ABM was to be detonated at high altitude and the radionuclides would receive worldwide distribution from the stratosphere.

Note that nearly all of the elements of the crusade were mounted in 1968-1969, a very busy period for Dr. Sternglass and for all of the biomedical community, which had relaxed somewhat regarding fallout problems. Every aspect required checking out.

First, we should note that the doses involved were never quantitated except for the early work with x rays. It was Sternglass's view that the effects were due to doses far too low to be measured reliably. The thousandfold or more greater sensitivity of humans to low-level radiation that was Sternglass's primary thesis was not based on dosimetry but on the correlations between events. Radiobiologists are accustomed to relating effects to doses.

The chief areas brought into question can be put in three categories: (1) the source terms, (2) the epidemiology, and (3) the correlative basic radiobiology.

a. Questions Regarding the Source Terms

It was contended that the fallout frequently did not go where Dr. Sternglass said it did. This question was addressed in depth by John Harley of HASL in New York, the organization that had very intimate contact with the fallout measurements as we have seen in previous sections. We will begin with Harley's summary (Harley 1969) of the points he was addressing:

There are three ways in which Dr. Sternglass has used strontium-90 fallout for his correlations.

1. He stated that the fallout from the Trinity Test at Alamogordo in 1945 went from west to east across Texas, Arkansas, Louisiana, Mississippi, Alabama, Georgia and the Carolinas. He stated that there was no immediate effect but that an excess in infant mortality of up to one child per hundred live births occurred five years later.

2. He stated that excess infant mortality began to appear in 1950-1951 in the wet metropolitan states of Massachusetts, Pennsylvania, Illinois, and New York, and the wet rural states of Georgia, Mississippi, Missouri and Louisiana following nuclear tests in Nevada. On the other hand, the dry rural states of Wyoming, New Mexico, Idaho and Colorado did not show excess infant mortality until after the thermonuclear tests of 1954 and 1958. In both cases, he claimed that the "excess infant mortality" began as soon as fallout occurred.

3. He correlated his "excess infant mortality" for six states where strontium-90 in milk was measured by the Public Health Service from 1957 on. He also correlated the nation-wide "excess infant mortality" with the total amount of strontium-90 produced in weapons tests, with the average strontium-90 in U.S. milk and with the amount of strontium-90 deposited in the northern hemisphere.

(Harley 1969, p. I-3)

With regard to the use of fallout data for Trinity, Harley points out that:

The trajectory of the 1945 Alamogordo Test has been plotted for winds at the 10,000, 20,000 and 30,000 ft. levels. These would indicate that the majority of the fallout would have been deposited in New Mexico and that the cloud would have crossed the state towards the northeast, going into Kansas and Nebraska. The portion of the cloud at 30,000 ft. did start toward the southeast but turned back into Texas without crossing the Mississippi.

(Harley 1969, p. I-4)

Harley further cites the data from soil samples and the fact that they show no anomalies. Thus, in his opinion, there is no reason to suspect that the fallout pattern predicted by the trajectory is in error, and it is quite different from that stated by Sternglass.

Regarding the second use of fallout data, Harley points out that the distinction between "wet" and "dry" states was developed by the FRC (see section VII) to apply to stratospheric fallout. The pattern from the early Nevada tests was quite different. The general trajectory was from tropospheric winds (see sections V and VI). Some of the "dry" states in the FRC nomenclature received much more fallout from NTS than states designated as "wet." The ^{90}Sr deposition in the United States before 1954 as determined by HASL is shown in figure 12.29 (Harley 1969).

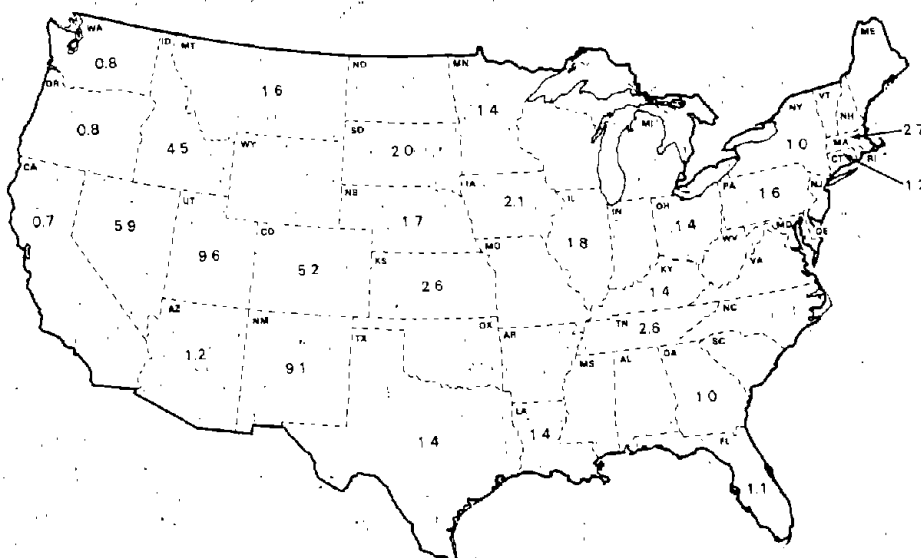

FIGURE 12.29. Strontium-90 deposition before 1954, based on gummed film measurements (mCi/m^2). (Redrawn from Harley 1969.)

Thus, there seem to be some curious inconsistencies in the data with regard to where the fallout went. Sternglass responded that he used information from the U.S. Weather Bureau and considered it equally reliable to that quoted by Harley. There is more of the same in other criticisms and rebuttals regarding the source term.

b. Epidemiologic Questions

Considering the data on milk, Harley was puzzled by the fact that the peak mortality rates Sternglass used lagged the peak concentrations in milk by five years, while "they supposedly follow ^{90}Sr deposition levels immediately in other graphs prepared by Dr. Sternglass" (Harley 1969, p. 1-7). As we will see below, the reported times of onset of the "excess mortality" were so variable that a logical epidemiologic study was very difficult.

Furthermore, in the report already cited, Harley comments that it is difficult to see how a test explosion the size of the Trinity shot could give rise to excess infant mortality at the level of one per hundred without the later test yields that

were a factor of 10^4 higher producing almost 100% mortality. There was also the fact that the mortality effect proposed by Sternglass occurred in 1950, five years after the Trinity shot. Since the heaviest period of fallout in the Northern Hemisphere occurred in 1962–1963, there should have been, for consistency, very high infant death rates in 1967–1968. In fact, the mortality rate was lower than that expected from the immediately preceding years. There were some particularly knotty problems regarding the data for New York State, especially the Albany-Troy area, which Sternglass had singled out as a clear example. Dr. Peter Greenwald, Director of the Bureau of Cancer Control of the New York State Department of Health, was asked to comment on the Albany-Troy data in connection with plans for a symposium of pediatricians. He stated in a letter (Greenwald 1969)^(a) that one of the key sources of data on the leukemia incidence in children, prepared by the New York State Health Department (Lade 1964), was in error. The questions raised are quoted below.

I would like to draw your attention to Table I^(b) of the *Science* article labeled "Cases of Leukemia in Children Under 15 Years of Age Reported in Albany, Rensselaer and Schenectady Counties, New York." While it is unfortunate that this Health Department may have erred in not clearly describing the possible inaccuracies in this table, it is clear that they should now be pointed out. The problems with these data and thus with the Sternglass paper are as follows:

1. The cases are listed by year of report. The year of report may well be different than the year of diagnosis, although I would judge by looking through a few case report cards in 1955 that the variation is not more than 1 or 2 years. There were two factors that could have influenced the quality of reporting in the early and mid-1950's. First, Dr. Kenneth Olson of the Albany Medical School began a registry for his hospital in 1952. Second, cancer case reports were not tabulated by the New York State Health Department in either 1954 or 1956. These are the only two years since 1940 that cases were not tabulated during the year of report. The reports for these two years were tabulated in retrospect in the early 1960's. The two above factors might influence year of report. They would probably not influence the total number of cases, since all persons who do not move after time of report should be identified through death certificates.

2. The place of residence refers to the residence of the child at the time the leukemia was reported. This may vary considerably from the place of residence of the mother at the time of the child's birth.

3. The year of birth for this table was derived by subtracting the reported age of the child with leukemia from the year in which the case was reported. This means that the year of birth could easily be off by one or more years.

4. In order to assess the extent of items 2 and 3 above, this Bureau examined the case reports, death certificates and birth certificates, when available, of the eight cases listed in table 1 as having been born in 1953. Two additional cases were identified who were born in the tri-county area in 1953 and who were reported to have leukemia after the time of the *Science* publication. The results of the review are shown in table A (enclosed). You will note that for only three of the eight cases did the mother reside in the tri-county area at the time of birth, and was the child truly born in 1953. Three of the remaining 5 persons were born in a different year—either 1952 or 1954; one was born in New Mexico; and one was born in a different county in New York State.

(a) There was also a full report by Greenwald and Kirsch entitled "Is There Evidence for an Association of Radioactive Fallout to Leukemia and Fetal Mortality in New York State?" but this author has only an undated manuscript copy of this.

(b) The tables referred to are shown as note 6 at the end of this chapter.

5. You will also note from table 1 that many of the cases have a lymphocytic histologic type, according to the case report card or the death certificate. It is my understanding that lymphocytic type leukemia has not definitely been associated with radiation exposure.

6. Case #2 (JP) was born by Caesarian section, raising the possibility of prenatal diagnostic X-ray exposure to this child. According to the birth certificate, case #2 was born after 37 weeks gestation and weighed 8 pounds. (Greenwald 1969)

Obviously, Sternglass could hardly be faulted for the fact that some of the mortality statistics he used were faulty. However, it appears that he was fully informed of the problems, yet never modified his position.

One of the more extensive analyses of the epidemiology was the one already cited sponsored by the PHS (Tomkins and Brown 1969). The report is too detailed for full description here, especially since there is no summary or conclusions. The last paragraph of the discussion section gives the flavor of the report:

The rate of decline of infant mortality in the United States did change around 1950. This lowering of the rate of decline has been a concern of many people working in the public health field. Many careful studies have been made, and no single factor nor group of factors have been identified which explain this change. While the hypothesis that this change is a result of ^{90}Sr deposition from fallout is an interesting one, the data presented do not appear to indicate any relationship between the change in rate of decline of infant mortality and the deposition of fallout in the United States.

Investigators in the United Kingdom entered the fray also. Lindop and Rotblat (1969) from the medical college of St. Bartholomew's Hospital in London examined each facet of the papers presented by Sternglass at the Hanford biology symposium and at the 1969 meeting of the Health Physics Society. They were puzzled among other things by the fact that, if it takes four years for the effect to manifest itself, why should it begin to decrease as soon as the ^{90}Sr began to decrease? A genetic effect would be expected to continue for a long time after cessation of the tests. They had problems with the statistics also.

Investigators in Canada were puzzled by the fact that although their ^{90}Sr levels were somewhat higher than in the United States, they did not seem to have any effect on infant mortality (Shaw and Smith 1970).

Other questions that were raised concerned the possible influence of other environmental factors, for example the presence of rubella and polio epidemics in 1953 and of measles and mumps epidemics in 1954 in Albany County, New York. These same types of problems were raised for other cities and states. They all come down to the problem of selection of a single factor from a galaxy of possible factors, one of the prime problems with retrospective epidemiology. Nevertheless, all that could be done was to point to the *possibility* that these other factors might play a role. There could be no solid proof for any single causative agent.

One of the more balanced reviews of the entire situation and the possible role of several environmental factors is contained in a critique by Arthur Tamplin and colleagues, then at the LLL. The abstract of this report is reproduced in its entirety below.

This report examines the data and conclusion of the Sternglass article in the May issue of the *Bulletin of Atomic Scientists*. In that article Sternglass purports to show that fallout radiation has increased infant and fetal mortality by 60 or more percent.

In this report, we undertake a critical review of that article and show that the data do not support his conclusions. This report demonstrates that the *major* factors influencing infant and fetal mortality over the past 50 years have been improving social-economic conditions and the introduction of antibiotics.

The available data on infant and fetal mortality and the supporting collateral data demonstrate that the worldwide differences in these mortality rates are a result of differing social-economic conditions. They indicate that the major factor that could improve the mortality rates in the United States is improvement of the social-economic conditions of the poor. They show that middle-class Americans enjoy the lowest mortality rates in the world and indicate that increased medical care would probably have little effect on the mortality rates of the poor; that an economic transfusion is needed, and that even then it would require at least a generation to bring the rates to parity.

At the same time, the existing experimental data indicate that fallout radiation probably did contribute to infant and fetal mortality by way of lethal mutations but nowhere near the effect suggested by Sternglass. The effect is most likely at least a factor of 100 smaller than he proposes. Moreover, in terms of non-lethal but deleterious mutations, the data suggest that it is now too early to look for the effect. This latter effect would be expected in 1980-1985 when the children born during the 1960-1965 era reach child-bearing age. It is impossible to estimate this aspect of the problem. Even then it might prove impossible to determine the effect from the death rate data because, in the 1980-1985 period, we may be observing the full brunt of the effect of the wide variety of environmental pollutants that have plagued this group of new parents from conception to child-bearing age. It may be that fallout radiation will represent only the top of the iceberg. (Tamplin, Ricker, and Longmate 1969)

c. Correlative Radiobiological Questions

Let us turn briefly to some nonepidemiologic considerations.

1. The genetic dose to man from ^{90}Sr is quite small compared to the dose to bone and bone marrow. Swedish work (Lüning et al. 1963a,b) did indeed implicate ^{90}Sr as a cause of fetal death in mice. However, Brues pointed out that this was due most probably to irradiation of the gonads by beta particles from the skeleton near the gonads, not from deposits of ^{90}Sr in the germ cells of the gonads. In man, the gonads are beyond the range of the beta rays produced from ^{90}Sr in bone. An alternative, direct genetic effect on the germ cells cannot be conclusively eliminated, except to say that no such effects have been seen in animal experiments at much higher doses.
2. Good experimental data with an important implication to the possible role of fallout and ^{90}Sr come from the large experiment with pigs at Hanford (see chapters 8 and 13), which were fed large doses of ^{90}Sr daily for years. Neither the parents nor their offspring exhibited effects on reproductive capacity, even at levels high enough to produce bone cancer, lymphoid disorders, etc. In fact, there were no malformations or stillbirths in the experiment. Dr. Sternglass takes the view that animal data are not pertinent, that only man shows the exquisite sensitivity to low-level radiation called for by his hypotheses.

3. Comment

Despite the volume and stridency of the critiques, Sternglass remained undaunted. He prepared rebuttals for many of the points, which can be reviewed in his book issued in 1972 (Sternglass 1972a). If things seemed to be going badly for one set of data, he would frequently appear with analyses applied to new

situations, but using the same basic techniques and arguments. Thus, as the fallout issues receded, he applied the same general approach to emissions from nuclear power plants and cited excess infant mortality around operating nuclear reactors as well as many other facilities involving radiation or radioactive materials.

He became interested in the cell membrane and proposed effects of very low-level radiation doses on it in a paper at the fourteenth Hanford biology symposium (Sternglass 1976). It is getting us too far from radionuclides and fallout to go further here, except to remark that some implications of the membrane effects were discussed by Stannard in the same volume (Stannard 1976).

The Sternglass crusade was extended to questioning the adequacy of the AEC's limits for exposure of the public to effluents from nuclear facilities, an area where Dr. Sternglass had much more company than he did for his fallout proposals. The data used concerned infant mortality around the Dresden I reactor in Illinois, the Big Rock Point facility in Michigan, the Humboldt Bay installation in California, the Indian Point plant and BNL in New York, and others. Most of these were presented at hearings or other legislative investigations and at a meeting of the Association of Physicists in Medicine (Sternglass 1972b). The references for the hearings presentation can be seen in two BNL reports (Hull and Shore 1971 and 1972), which include the usual critiques of the way the data were gathered and handled.

What conclusions can be drawn from all this? It must be obvious that there were and are many problems with the way the data were analyzed in attempts to support the hypotheses as well as with the data themselves. Yet, it is also obvious that Sternglass stimulated a comprehensive examination of infant and child mortality in the United States. Indeed, many of the problems with the data might never have been discovered except for the stimulus of his crusade.^(a) No one can prove conclusively that he is wrong, only that much more information would be needed to prove that he is right. An expression of this can be seen in the concluding paragraph of an editorial on Sternglass's work published in the McGraw Hill periodical *Scientific Research* (H.L.D. 1969).

The upshot of all this is that apparently no one has done a large-scale animal experiment with ingested Sr^{90} at the fallout dose levels the results of which could then be used to directly prove or disprove Sternglass's hypothesis. Until someone does we can not be completely certain that some unthought-of low-level effect does not exist. As Dyson expressed it, "The essential point is that we do not have a firm upper limit to the infant mortality caused by fallout. Although Sternglass's argument may be 'sloppy' we have no proof that his conclusion is wrong."

This was in 1969. Has work over the intervening years provided conclusive answers? In a sense it has to the degree that the exquisite sensitivity proposed by Sternglass has not yet appeared in experimental work. Yet, all experiments are at higher doses, and an inhibiting effect of these higher doses cannot be

(a) These statements should not be interpreted as indicating that the whole episode was a net gain. The value of the research interrupted or never done in other areas while investigators dropped everything to respond to Sternglass's allegations can never be ascertained. In this author's opinion, it would be considerable. Nevertheless, we cannot gainsay attempts to salvage something of value to science from the enormous volume of attacks and counterattacks involved.

conclusively denied. It would take an experiment with millions of animals to do what is required in the editorial just quoted.

Let us conclude by quoting from an extensive comment by Boffey in the "News and Comment" section of *Science* (Boffey 1969).

The Sternglass case has raised the perplexing question of whether it is "good" or "bad" to have a scientist yelling "fire" when there may not be any fire at all. On the negative side, some critics contend that Sternglass, by alarming the public without reason, has made it more difficult to reach rational decisions on such important issues as the ABM and nuclear power. Others contend that, if Sternglass is ultimately shown to be a fool, the public's confidence in the scientific method will be diminished. And if Sternglass has actually made selective use of the data to support a preconceived theory—as some critics allege—that, of course, cannot be defended.

On balance, however, the country probably has more to gain than lose by letting Sternglass have his day in court. If Sternglass is right, he has performed an incalculable public service. But even if he is wrong—and the weight of informed opinion seems to think he is—he has nevertheless served a useful function by forcing others to look into the question.

We have already commented earlier and will again in chapter 21 on the surprising lack of experimental work on the genetic effects of deposited radionuclides. Only recently has serious work in reasonable volume been brought to bear in this area.

D. Progress

It is easy to cite in extenso the problems and dilemmas brought upon us by the testing of nuclear weapons, especially if one is writing from the standpoint of the biomedical community. It is more difficult to cite scientific and technical progress that was made as a result of the enterprise. Most of the progress is in the realm of basic research and has been described in earlier chapters or will be in chapters 13, 15, 21, and elsewhere. For the moment, let us list a few areas of pertinence.

1. Weapons Design and Efficiency

This area should be the one where the testing enterprise produced the greatest technical progress. It is, of course, one we cannot discuss.

2. Movement of Radioisotopes in the Biosphere and Geosphere

While much information was gathered in connection with effluents from nuclear installations, there can be no doubt that the worldwide distribution of fallout radionuclides enabled the collection of information on ocean currents, the behavior of radionuclides in the sea, patterns of air distribution, the exchange phenomena between troposphere and stratosphere, latitude effects, etc., that would never have been obtained otherwise.

3. The Behavior of Radioisotopes in the Food Chain

Again, some information could have been gathered from deliberate experimental contaminations. Some was obtained in work around nuclear energy installations. But the decisive role of food-chain transfer processes came to light from the fallout investigations.

4. Behavior of Radionuclides in Animals and Plants and in Humans

Much of this work has been described in earlier chapters, or will be in chapter 13. Much was done without the stimulus of fallout. Yet, the large increases in resources and manpower thrown into the field made a significant difference in both the rate of accrual and extent of our knowledge. Some of the most interesting work involving discrimination factors, the movement of pairs of isotopes, the important role of chemical forms of both the radionuclide and the receptor might never have been done without the stimulus of the fallout problems.

5. Radioecology

Examination of the development of radioecology described in chapter 11 makes it clear that the field was considerably advanced by the work involving fallout, even though it had its beginnings in work around nuclear energy sites.

6. Biological Effects of Deposited Radionuclides

Much of our knowledge of the effects of deposited radionuclides was already accrued when the fallout problems came upon the scene. The major large experiments were already under way with some exceptions. Yet, there can be no doubt that all such work was better supported and stimulated more interest because of the problems of fallout from testing of nuclear weapons. In the next chapter, we will review briefly some of the biomedical research that can be characterized as arising out of the problems of fallout.

IX. Summary and Commentary

Of the three new dimensions designated in this book for overt discussion, this third one was perhaps the least anticipated or prepared for and had the widest consequences beyond the world of science. The possibility of phenomena we now designate as fallout was definitely considered before the first nuclear weapons test at Alamogordo, New Mexico. Teams were outfitted to try to follow the fission product cloud. Preparations were even made to evacuate one or more of the nearest towns if needed. This was found unnecessary, but the existence of fallout and of residual contamination was fully established by this very first shot.

Fallout played a minor role in the bombings of Japan, although it was not completely absent. The detonations were at sufficiently high altitude to avoid contact of the fireball with the earth's surface. Perhaps for this reason, the phenomena of fallout came as more of a surprise when the weapons testing program began than they would have otherwise.

Operation Crossroads, in July 1946, opened everyone's eyes to the potential for contamination from fallout. The underwater shot (Test Baker) rained tons of highly radioactive water on the test fleet and made the ships uninhabitable for appreciable periods. In the U.S. Navy, it generated the need for a laboratory to concentrate on such contamination phenomena. Thus, the NRDL was organized and launched.

When it became clear that the United States no longer had a monopoly on atomic energy and atomic weapons, the central Pacific area, instead of shutting down, became the "Pacific Proving Grounds," and a continental site, the

"Nevada Test Site," was developed for "smaller" devices to reduce the problems of transportation over many thousands of miles. Nearly 300,000 kt of energy equivalent were released in airborne tests beginning in 1945, and the problems of fallout inevitably followed.

As part of these activities, resurveys were conducted early of sites such as Bikini (Operation Crossroads) and Alamogordo (Trinity shot). Biologists from the University of Washington were especially active in the former; personnel from UCLA in the latter. They found that the Trinity fallout had gone considerably farther than the original measurements indicated. Even a year after the operation, contamination of the Bikini lagoon and its biota was far from negligible, and the concentrations in certain aquatic forms was found to be quite high.

In theory, it was thought that the fallout from the fission tests at NTS would remain largely onsite. This was, of course, found to be quite wrong. Not only were there the incidences of contamination of communities in Nevada and Utah and entry of fallout radionuclides into food chains, particularly milk, but the clouds occasionally traveled across the entire country and produced local rain-out or snow-out in the northeastern sections in line with prevailing weather patterns.

With the advent of the testing of thermonuclear weapons, the dimensions of the fallout problem were widened enormously. These devices had enough energy to inject radioactive products into the stratosphere, where they were retained for appreciable periods and gradually distributed latitudinally as well as longitudinally. Thus began the problems of worldwide fallout from nuclear weapons tests, with movement in the upper atmosphere and gradual exchange between stratosphere and troposphere, all added to the tropospheric movement known earlier. The biomedical significance of ^{89}Sr and ^{90}Sr and of iodine in air and in food and water and other radionuclides in the environment required enormous efforts at collection and analysis (this chapter) and experimental studies of effects (chapter 13). Indeed, the biomedical community found itself in the midst of a first-class crisis, where knowledge fell far short of needs.

The importance of fallout was especially underscored by the notorious Shot Bravo in the Castle series in the Pacific. This was the thermonuclear shot that contaminated the Marshall Islands and many of the inhabitants, as well as U.S. servicemen, the Japanese fishing boat *Lucky Dragon*, and produced an uproar in Japan regarding potential contamination of their seafood sources.

From this point on, scientific problems of fallout, both its behavior and effects, had to be explored side-by-side with growing political, even moral, issues. Many of these led eventually to litigation both in the continental United States and in the Pacific and enormously expensive efforts concerning the repatriation of the Marshallese and the care of those who had been exposed. These events are described in moderate detail, including all but the most recent decisions and actions.

Despite the strident nonscientific problems, including debates on whether or not testing should ever have been engaged in at all, much new scientific knowledge was gained as a result of all of these efforts. In chapter 13, we will review much of the *de novo* research stimulated by the problems of fallout. Yet, much was also learned in the field work described herein. The kinetics of movement of radionuclides in local, regional, and worldwide environments were studied with an intensity undreamed of before. This included atmospheric transport phenomena, aquatic transport, and the more obvious terrestrial systems. Unlike the experiments involving the acute effects of external radiation from the shots,

the potential for effects from radionuclides came in for much longer-term study. In fact, it is the potential of these early exposures for producing cancer decades later that now sustains attention on the problems of fallout, even though the amounts now remaining are very small.

The chapter digresses slightly from the central theme with a discussion of the standards developed for exposure to fallout, including whether or not the common practice of assuming that protection against the external radiation dose really sufficed to protect against the effects of long-term exposure via deposited radionuclides. Also, the allegations of E. Sternglass, which began around a proposed correlation between infant mortality in various sections of the United States and exposure to fallout radionuclides, are reviewed in some depth.

The chapter concludes with a listing of some of the positive correlates of this enormous endeavor. Naturally, what we learned concerning one of the primary reasons for the tests, i.e., weapons design and efficiency, cannot be discussed or evaluated since the information remains unavailable to the public, including the biomedical community.

Table of contents of book by Petrov et al. USSR on Radioactive Fallout—Physics, Biological Effects, and Protective Measures

TABLE OF CONTENTS	
1966	
Preface	vii
I. Nuclear and Thermonuclear Explosions	1
II. Atomic Cloud	7
Fireball and explosion-produced funnel	7
Formation of the cloud	7
Atomic cloud particles	8
Fallout from an atomic cloud	10
III. Formation of the Radioactive Wake	11
The cloud and the "tail"	11
Formation of the wake and fallout forecasting	12
Determination of the length and width of the radioactive wake in the case of a ground explosion	15
IV. Radioactive Products of a Nuclear Explosion	21
Fragments	21
Induced activity	23
Nuclear residues	23
V. Laws of the Radioactive Decay of the Fission Fragments	24

VI. Instruments and Methods of Field Dosimetry of Fragments	28
Design and general working principles of dosimeters (radiometers)	28
Measurement of gamma-radiation level	29
Measurement of the specific activity of a contaminated surface	30
Determination of the radioactive contamination of the air	31
Determination of the radioactive contamination of water	32
VII. Monitoring of the Radiation Environment	34
Overall estimate of the radiation situation during local fallout	35
Determination of the degree of radioactive contamination of air, soil, and water	37
Detailed estimate of the radiation situation during local fallout	38
Determination of the age of fragments	38
Determination of the gamma-radiation dose rate at any moment after the fallout of fragments	40
Determination of the total gamma-radiation dose	42
Determination of the gamma-radiation dose of fragments during any time interval	43
Determination of the degree of contamination of a territory by different isotopes	45
VIII. Biological Effects of External Irradiation	47
Characterization of the damage in the case of general external gamma-irradiation	47
Beta-burns from fallout of radioactive substances on the skin	49
Recovery processes	49
Determination of the magnitude of net injury and of the rate of recovery. Blair's theory	52
Rate of recovery of man	54
Justified-risk doses in extreme conditions	56
IX. Practical Problems of Protection and Shielding During Local Radioactive Fallout	57
Radiation injury and recovery in the case of chronic irradiation	57
Quantitative characteristics of the process	57
Determination of the biologically effective dose	59
Evacuation or shelter	60
Determination of the shielding factor necessary to reduce the effective dose	62
Determination of a maximum permissible duration of irradiation	64
Determination of the return time to a contaminated territory (re-entry time)	65
Calculation of permissible repeated-irradiation doses in extreme conditions	67
X. Effect of Radioactive Substances Entering the Organism	71
Most dangerous radioisotopes	71
Justified-risk dose in the case of entrance of radioactive substances into the organism in extreme conditions	73
XI. Measures for Defense against Radioactive Fallout	75
Defense Measures	75
Individual means of protection	78
Decontamination	78
Appendix 1. Yield of some isotopes formed by the fission of uranium-235 by thermal neutrons (n_T); uranium-235, plutonium-239, and uranium-238 by fission neutrons (n_f); and uranium-235 and uranium-238 by 14 Mev neutrons (n_{14})	80

Appendix 2. Characteristics of the main fission products	81
Appendix 3. Characteristics of the basic products of soil activation	86
Appendix 4. Activity and energy of the gamma-radiation of fragment isotopes for various times elapsed from the fission (for uranium-235)	87
Appendix 5. Mathematical expression of the law of radioactive decay of fragments and its application to the solution of some problems	115
Appendix 6. Mathematical expression for the biologically effective dose	118
Appendix 7. Field dosimeter-radiometers manufactured in the USSR	120
Appendix 8. Symbols and units of measure	131
Bibliography	133

Note 5

Federal Radiation Council

Members

Secretary of Health, Education, and Welfare (Chairman)
Secretary of Agriculture
Secretary of Commerce
Secretary of Defense
Secretary of Labor
Chairman, Atomic Energy Commission
Special Assistant to the President for Science and Technology (Adviser)

Staff

P. C. Tompkins, Executive Director
C. C. Palmiter, Special Assistant

Working Group

F. A. Todd, Department of Agriculture
H. O. Wyckoff, Department of Commerce
G. L. Hekhuis, Department of Defense
J. G. Terrill, Jr., Department of Health, Education, and Welfare
J. P. O'Neill, Department of Labor
F. Western, Atomic Energy Commission

National Academy of Sciences - National Research Council

Advisory Committee to the Federal Radiation Council

A. C. Upton (Chairman), Oak Ridge National Laboratory
H. L. Andrews, National Institutes of Health
V. P. Bond, Brookhaven National Laboratory
C. L. Comar, Cornell University
J. F. Crow, University of Wisconsin
S. P. Hicks, University of Michigan
B. MacMahon, Harvard School of Public Health
J. E. Rall, National Institutes of Health
W. L. Russell, Oak Ridge National Laboratory
E. L. Saenger, University of Cincinnati
Shields Warren, New England Deaconess Hospital

Ad Hoc Panel on Environmental Factors

A. H. Wolff (Chairman), U.S. Public Health Service
B. R. Bruckner, U.S. Public Health Service
J. J. Davis, Atomic Energy Commission
G. F. Fries, Department of Agriculture

W. C. Hanson, Battelle-Northwest Laboratory
 J. Harley, Health and Safety Laboratory (AEC)
 F. P. Hungate, Battelle-Northwest Laboratory
 F. W. Lengemann, Cornell University
 T. F. McCraw, Atomic Energy Commission
 J. Rivera, Health and Safety Laboratory (AEC)
 D. G. Watson, Battelle-Northwest Laboratory

Ad Hoc Dosimetry Panel

W. S. Snyder (Chairman), Oak Ridge National Laboratory
 C. W. Mays, University of Utah
 W. P. Norris, Argonne National Laboratory
 J. Rivera, Health and Safety Laboratory (AEC)
 H. Q. Woodard, Sloan-Kettering Institute

Note 6

Tables excerpted and modified slightly from letter by Peter Greenwald (1969)
 [see text, section VIII C]

Table A. Eight Persons Who Developed Leukemia Who are Listed by Sternglass as Being Born in 1953 and Residing in Albany, Schenectady or Rensselaer Counties and Two Later Cases

Initials	Date of Birth	Residence of Mother at Time of Birth (County or State)	Year of Leukemia Report	Histologic Type from Death Certificate or Case Report Card	Father's Occupation from Birth Certificate	Remarks
A. Cases truly born in 1953 with mother residing in tri-county area.						
1. WR	3/27/53	Rensselaer	1954	Lympho-blastic	Machine Operator, Watervliet Arsenal	
2. JP	6/8/53	Albany	1960	Acute Leukemia	Mechanic-Chemical	Caesarean Birth
3. EW	8/25/53	Albany	1956	Leukemia	Tool Grinder, Watervliet Arsenal	
B. Cases truly born in a year other than 1953, or mother residing outside tri-county area.						
4. MG	5/23/52	Schenectady	1962	Acute Lymphocytic	Accumulator, General Electric	
5. DA	5/25/52	Albany	1956	Acute Lymphatic	Painter-Mechanic, NY Central RR	
6. DC	3/12/54	Albany	1957	Acute Lymphocytic	Foreman, Coleman Heal & Wedge Co.	
7. CP	5/31/53	New Mexico(a)	1957	Acute Lymphatic	Unknown	

TABLE A. Continued

Initials	Date of Birth	Residence of Mother at Time of Birth (County or State)	Year of Leukemia Report	Histologic Type from Death Cert. or Case Report Card	Father's Occupation from Birth Certificate	Remarks
8. DS	8/9/53	Montgomery Co., NY	1961	Lympho-blastic	Machinist, General Electric	
C. Cases truly born in 1953 with mother residing in tri-county area and not reported by Dr. Sternglass.						
9. HW	9/27/53	Schenectady(b)	1964	Acute Granulocytic	Unknown	Adopted Child
10. RG	11/6/53	Albany	1965	Granulocytic	Printer, Williams Press	

(a) Place of birth of child; mother's residence at time of birth unknown.

(b) Place of birth of child; mother's residence at time of birth unknown because of adoption.

Table B. Number of Cases of Selected Infectious Diseases Reported to the Albany County Health Department, 1951-1955

Disease	1951	1952	1953	1954	1955
Rubella	29	104	994	108	21
Measles	2459	437	100	1268	1529
Chicken Pox	487	486	614	634	596
Mumps	277	108	208	500	51
Hepatitis	14	3	212	390	73
Polio	23	8	46	25	24

OUTLINE BIOMEDICAL RESEARCH STIMULATED BY THE PROBLEMS OF FALLOUT

Capsule Chronology	1059
Overview	1063
I. New Laboratories	1064
A. The U.S. Naval Radiological Defense Laboratory	1064
B. The University of Tennessee-AEC Agricultural and Research Programs	1069
C. Cornell University	1074
D. University of California at Davis, Radiobiology Laboratory and Later Laboratory of Energy Related Health Research	1076
E. Southwestern Radiological Health Laboratory	1077
F. Other U.S. Public Health Service Laboratories	1080
II. Special Programs at Established Laboratories	1081
A. Argonne National Laboratory	1081
B. University of California at Berkeley	1083
C. Brookhaven National Laboratory	1084
D. Battelle, Pacific Northwest Laboratories (Hanford)	1085
1. The Experiment with Strontium-90 in Swine	1085
2. Radiostrontium Studies in Pygmy Goats	1087
3. Passage of Pairs of Elements Through Food Chains	1087
4. Radionuclides in the Fetal and Juvenile Mammal	1087
5. Research with Plants	1087
6. Aquatic Biology and Marine Sciences	1087
E. Los Alamos Scientific Laboratory, Now Los Alamos National Laboratory	1088
F. University of California at Los Angeles	1089
G. University of Rochester	1089

Capsule Chronology

- 1945** Alamogordo (Trinity) cattle go to Oak Ridge.
- July 1946** Results of Operation Crossroads generate need for laboratory devoted to such problems. Lead to organization of Naval Radiological Defense Laboratory (NRDL)^(a) at San Francisco.
- Aquatic biology of radionuclides gets boost for both laboratory and field studies.
- November 1946** NRDL begins work on small scale.
- 1947 et seq.** Work on mice by M. Finkel (Argonne) expands. Later includes special experiment on radiostrontium. Continues into 1970s.
- 1948** AEC lets contract with University of Tennessee Agricultural Research Laboratory, theoretically for further follow-up of Alamogordo cattle, but soon becomes much broader. Cyril Comar appointed as director. Staff includes Lengemann and Wasserman, Hood and Hansard. Called UT-AEC Farm.
- 1949** Nine projects already under way at UT-AEC.
- NRDL becomes more biomedical and expands.
- 1950** Utah project organized. Work not initially oriented toward fallout problems but expanded later to include them (details in chapter 8).
- 1950s et seq.** UCLA project concentrates on laboratory and glasshouse experiments relevant to fallout radionuclides.
- 1950s** Work starts at Berkeley on ^{90}Sr in rhesus monkey (Durbin).
- Studies at Hanford begin on uptake and translocation of fission products by plants; continues indefinitely and expands to transuranics.
- Hanford study of ^{90}Sr in miniature swine (Bustad, McClellan, and Kornberg).
- Hanford studies on passage of pairs of elements through soil and food chains (Kornberg and Thompson).
- Hanford studies on fallout radionuclides in fetal and juvenile mammal (Sikov and Mahlum).
- Comar et al. develop Observed Ratio (OR) approach to describe relative behavior of pairs of elements (UT-AEC). Used extensively to describe metabolism of fallout radionuclides. Sometimes carried too far. Discrimination processes and discrimination factors much emphasized.
- Laboratory work on diets confirms and extends findings from the field.
- 1956** University of California-Davis project organized primarily for feeding of radiostrontium to beagles, but other dimensions added.

(a) For abbreviations and acronyms, see Appendix D.

- 1957** Cyril Comar goes to Cornell University to establish Department of Physical Biology and radiobiology program, including effects as well as mineral metabolism.

Experimental work with plants indicates same basic behavior of isotopes as in animals (Romney et al., UCLA). Clear that much of the absorption of radionuclides by plants is foliar. Amplified by subsequent work in many other laboratories.

Chapters on laboratory experiments with marine organisms in NAS-NRC report on oceanography and fisheries (see chapter 11).

- 1958** Oak Ridge work becomes quite experimental.

Studies begin on radiostrontium behavior in man (Spencer et al.).

- 1959** PHS establishes regional radiological health facilities. The one at Las Vegas is especially involved in research stimulated by the problems of fallout (named Southwestern Radiological Health Laboratory—SWRHL). Work on radionuclides seen in fallout carried out also at Radionuclide Toxicity Laboratory in Robert A. Taft Center in Cincinnati. Later moved to Rockville, Maryland. Other regional laboratories are described in chapter 11.

- 1960** Minnesota symposium contains many reports on experimental work stimulated by the problems of fallout.

Successive generation plant work at UCLA indicates gradual changes in solubility of radionuclides (Romney et al., UCLA).

- 1960s.** UT-AEC work confirms in large animals most of the earlier findings in small animals concerning fallout radionuclides.

Brookhaven work shows real differences among responses of higher plants and animals to radiation.

Rochester work on strontium in monkeys and rats (Casarett and Tuttle), also renal clearance (Della Rosa, Smith, and Stannard) and life-span shortening (Blair).

Brookhaven whole-body counting facility brought to bear on many problems of radionuclides from fallout in man and animals (Cohn et al.).

Argonne National Laboratory experiments with cesium in dogs.

- 1961** Lovelace facility initiated. Centers on many inhalation problems (chapter 9) but uses radionuclides in fallout.

Much work on mechanisms of discrimination between elements.

Relation between nuclear volume and radiosensitivity of plants established (Sparrow, Brookhaven).

- 1963** An NAS-NRC BEAR report summarizes behavior of radionuclides from fallout in soils and plants.

Reports on tracer level studies of cesium in man (Spencer et al.).

- 1964** Reports of Los Alamos work on effects of various factors on behavior of fallout radionuclides.

- 1965** Book edited by Fowler (Los Alamos) has many reports of experimental work with fallout radionuclides.

Discrimination factors described for plants in different soils (Nishita, UCLA).

Much work on effects of diet and age on discrimination in animals and man (Comar et al., Cornell).

- 1966** Concluded that Alamogordo cattle possess normal breeding efficiency, but hyperkeratosis is evident (Brown, Bird et al., UT-AEC).

- 1967** Book, *Strontium Metabolism*, published in United Kingdom (Lenihan, Loutit, and Martin, eds.).

Stockholm Symposium on Radionuclide Concentration Processes (Åberg and Hungate, eds.). Contains review by Polikarpov on experimental work with aquatic forms. Also much work with plants.

Several laboratories develop whole-body counters for fish to investigate mobility of radionuclides.

- 1969** NRDL closed.

Laboratory studies of clam and quahog (Andrews and Warren; Rochester, Harvard).

Differences in metabolism as function of route of administration and other factors established for many radionuclides (McClellan and Jones).

Effects of strontium on farrowing performance of animals occur only at very high doses (Battelle, Lovelace).

- Late 1960s** UT-AEC Farm becomes Comparative Animal Research Laboratory (key staff—Brown, Bell, Miller, Mraz, Noonan, Reynolds, Spalding, Hansard).

- 1970** EPA takes over PHS-BRH regional laboratories. Programs continue.

- 1970s** Gradual shift from strontium, cesium, etc., to tritium, krypton, radium, and uranium from mill tailings.

- 1972** Strontium Symposium at University of California-Davis reviews large amount of experimental work stimulated by problems of fallout (Goldman and Bustad, eds.).

- 1976** Order of sensitivity of marine organisms described at IAEA symposium.

- 1977** NCRP report on experimental work with radiocesium over the previous decades.

- 1978** NCRP report summarizes experimental work on radiocerium.

- 1980** Much experimental work in book on transuranics edited by Hanson (see chapter 11).

- 1981** Review of experimental work on soils in issue of *Soil Science* (several laboratories).

Chapter 13

Biomedical Research Stimulated by the Problems of Fallout

Overview

This chapter concerns scientific experiments. With some exceptions, the activities described in chapter 12 were centered on *observations*, e.g., finding the facts about the behavior and possible effects of the radionuclides from weapons testing in elements of the biosphere. There was no control over the variables, just measurements.

To understand the results obtained, to be able to make more satisfactory predictions, and to be able perhaps to take some measure of remedial action, experimental work under controlled conditions was deemed essential. While the laboratory work of the Manhattan District and its early post-World War II extensions (chapters 6, 7, and 8) and the classic studies with naturally occurring radioisotopes (chapters 1 to 4) provided a long start, there were many problems more or less specific to the fallout situation that mandated equally specific experimental approaches. It is these that we will undertake to review in these pages.

"Experimental" in the context of this chapter means both laboratory and field-type investigations. So long as the plan was to manipulate certain variables while keeping others constant in order to observe the behavior or effects of radionuclides characteristic of fallout, we will define it as "research." Obviously, our choice of whether or not the output of certain programs is to be regarded as "stimulated by the problems of fallout" has had to be somewhat arbitrary. Since the same radionuclides are of biomedical importance in many contexts, there is inevitably overlap between the types of work we considered in chapter 8, work we have considered in connection with nuclear reactors,^(a) around production sites (chapter 11), and the work described in this chapter. Nevertheless this does not prevent us from selecting out the research that we deem most pertinent to the subject at hand.

(a) Much of the research begun around the problems of fallout has continued, of course, around more general problems of environmental contamination, including that from nuclear reactors.

As alluded to in earlier chapters, there were laboratories that came into being primarily to attack the problems raised by fallout. We consider them and their work first. In addition, the established laboratories modified or expanded their programs in order to attack some of the problem areas defined in chapter 12. Some laboratories, e.g., the University of California at Davis, were engaged in a general attack on radionuclide toxicity and pharmacokinetics, but the timing of their organization and results puts them neatly within the purview of the present discussions. For this reason, we promised in chapter 8 to review details of their findings here. Some laboratories underwent only perturbations in their programs, not major changes in direction (e.g. Argonne National Laboratory, University of Rochester). Every laboratory in the world with capability and interest in work concerning radionuclides in the biosphere participated in some way in research or surveillance concerned with fallout. To these we can devote only minor attention, but pertinent reviews will be cited.

Financial support for these enterprises came primarily from governmental agencies. The early efforts were supported largely by the military, particularly the U.S. Navy. Funds from the military continued to play an important role through agencies such as the Armed Forces Special Weapons Project and its successor, the Defense Nuclear Agency.^(a)

The Atomic Energy Commission played a central role both financially and in the provision of facilities and personnel. This was continued under the Energy Research and Development Administration and the Department of Energy. The U.S. Public Health Service also played a substantial role in research as it did in surveillance. The Public Health Service programs were taken over by the Environmental Protection Agency on its inception in 1970.

I. New Laboratories

We will take up the organization, mission, and broad programs of those laboratories created around the problems of fallout in approximate chronological order of their founding and development. Most details of the research findings will be discussed under the several headings in sections III and IV, since we need to consider the results en masse.

A. The U.S. Naval Radiological Defense Laboratory

The *raison d'être* for this laboratory lay in the tons of highly contaminated sea water that showered down upon the assembled flotilla of warships in Test Baker of Operation Crossroads (chapter 12) on July 25, 1946. As the still-contaminated ships limped back to the continental United States from Bikini Atoll, test personnel, made grimly aware that fallout contamination could be serious business, even lethal, urged the establishment of a laboratory group to search for urgently needed countermeasures. Thus, as R. A. Hinnens stated (1957)^(b) "like Venus, NRDL was born in the foam of the sea."

(a) Biomedical problems were, of course, only a small fraction of their total investment.

(b) I am indebted to Dr. C. Sharp Cook, Department of Physics, University of Texas at El Paso, for making this and other scarce reference material available to me. Dr. Cook spent several years at the Naval Radiological Defense Laboratory (NRDL) heading the Nucleonics Division. Captain Hinnens was Commanding Officer of NRDL from 1953 to 1956. Also Dr. Burton Vaughan, Battelle, and Dr. William Kreager, retired, supplied notes and references.

The ships moved, sometimes with intermediate stops, to the San Francisco Naval Shipyard on Hunters Point in San Francisco Bay. The presence there of a large Naval facility, some temporary buildings left over from World War II, and the proximity of educational institutions that might act as sources of both ideas and personnel fostered the decision to develop a laboratory there. Biomedical problems were not paramount in the minds of the founders. Decontamination was the pervasive issue. However, it soon became apparent that there were huge gaps in our knowledge regarding the biological effects of moderate to large doses of whole-body radiation,^(a) particularly effects that might bear on the ability of military personnel to carry out their missions. Also, there was concern over problems of food and water contamination, what to do about the extremely "hot" fouling organisms that could turn the sides of a ship into extended radiation sources (chapter 12), and other quasi-biomedical problems. Thus, very soon the organizational plan called for close collaboration between physical and biological scientists. While the facility was developed under the Bureau of Ships of the U.S. Navy, it was planned that the Bureau of Medicine and Surgery would supply personnel and funds and utilize the facilities for studies of radiological hazards.

Obviously, the laboratory did not start with such cooperation in place. Indeed, the laboratory consisted initially of a few junior officers, a few Geiger counters, some scalars, mostly borrowed (Hinnens 1957), and the all-important coffee urn. This was in November 1946.

From this grew an organization that was eventually housed in a multimillion-dollar facility with four major scientific divisions, one of which was "Biological and Medical Sciences." The program of the laboratory as of 1959 (OPNAV Report 1959)^(b) was outlined as follows:

Current Program

In its growth and development the seven broad phases of the scientific program now cover:

1. Determination of the characteristics of harmful radiations and radioactive materials.
2. Study of atomic explosion phenomenology and weapons effects.
3. Study of hazards of nuclear radiations to personnel.
4. Development of instruments to detect, identify and measure radioactivity.
5. Development of countermeasures for removing radioactive contamination and for minimizing or preventing contamination.
6. Study of measures to minimize harmful effects of nuclear radiation on human beings.
7. Study of physical and biological effects of thermal radiations accompanying nuclear weapons detonations.

We saw in chapter 12 that personnel from NRDL had much to do with the Pacific tests, including study of the exposed Marshallese. This gave them first-hand experience that could influence their laboratory research and vice versa. As already noted (see also chapter 19), development of chelation therapy for

(a) Most of the emphasis for protection had been on occupational exposures or on the procedures used in radiation therapy and diagnostic radiology.

(b) I am indebted to Dr. Dean Allard, Navy Historian's Office, Navy Yard, Washington, D.C., for facilitating my review at that facility of eleven reports on the history of the NRDL and for preparing copies of unclassified excerpts. The 1959 report cited covers the period 1946-1958.

removal of deposited radionuclides was included in the early work of the NRDL biomedical program and constituted a clear interaction of field and laboratory.

In the chapter on inhalation toxicology (chapter 9), we met work, especially by Cohn and Gong, on inhalation of a fallout simulant by animals. In chapter 3, we saw that these same authors even took a foray into the problems of radon and radon daughters.^(a)

Much emphasis in the NRDL program went to external radiation sources, both ionizing and thermal. The cited summary report reviews the biomedical program of the time (1958) as follows:

Biological and Medical Sciences. This division is involved with problems of injury to personnel resulting from nuclear and thermal radiation. From the earliest days of the Laboratory, biologists and doctors of medicine have been studying the complex relationships between radiation and the organism. Experimental animals, mostly rats and mice, have been used in a great variety of basic studies, most of which are too esoteric for discussion here. The general aim of this work, however, is to learn the nature of radiation injury; how to prevent it, and how to treat it, ultimately in the human.

Early difficulties and disappointments with animal studies at Operation GREENHOUSE and BUSTER/JANGLE led to the development of laboratory radiation sources for greater economy, efficiency, and control of experimental variables. These sources include many emitters of nuclear radiation as well as two particularly satisfactory thermal sources—the Mitchell carbon arc, whose energy is usually emitted in the form of a standardized simulation of a nuclear weapon's thermal pulse; and the 30-inch searchlight, whose energy, about three times that of the Mitchell, is normally controlled by a precise square-wave shutter on which staff members hold a patent.

Studies of rat skin burns developed into investigation of more profound systemic effects such as erythrocytic fragility and led to the first Thermal Burn Conference, held at NRDL in 1953. They also were expanded to include burns from beta particles from P^{32} , a Sr-Y plaque (with a longer half-life than P^{32}) which produces about 25 rads/sec, and electrons from the Van de Graaff accelerated over a wide energy range—from the machine's upper limit of 2 MeV down to levels at which the electrons will penetrate skin only to a depth of 100 microns. Volunteers have exposed themselves to first degree thermal burns and, with the required approval of the Secretary of the Navy, to low-level beta radiation, attempting to add to the small store of data on the human. At present, long-term inter-species comparisons using large mammals are under way, particularly with neutrons, again in an attempt to extrapolate, eventually, to the human. *In vitro* studies of the inhibition of synthesis of DNA (a basic cell material) by sodium ions, which as [sic] among the products of ionizing radiation, are of interest to the cancer researcher. Studies of avoidance conditioning, wherein animals will quickly learn to avoid a place where they were given low doses of x- or gamma radiation, raise interesting questions about their sensing the presence of radiation. Other work has shown that the liver, thought to be insensitive to radiation damage, shows a high percentage of mitotic anomalies when cell division is accelerated. Successful inter-species transplants of skin and bone marrow are provocative to those studying radiation therapy. (OPNAV 5750-5 [1959])

(a) This was not totally foreign to the Navy's mission. A tightly closed vessel, especially a submarine, with multitudinous instruments involving luminous paint, could accumulate sizeable concentrations of radon. Hence, this foray had significance beyond the problems of uranium mining that were the traditional arena for concerns about radon.

In a report for fiscal year 1969 (USNRDL 1968),^(a) the following biomedical research enterprises were listed. This was work sponsored by the Bureau of Medicine and Surgery and directed by Drs. E. Alpen and G. F. Leong:

1. Radiation effects on cellular regulation
2. Biochemical basis of radiation sensitivity
3. Ontogenesis of the immune response
4. Partial body radiation—biological effects of shielding
5. Radiation effects on gastrointestinal tract function
6. Therapeutics and modification of radiation injury in mammals by biological and chemical means
7. Hazards of airborne radioactive materials
8. Alteration in physiological functions following exposure to ionizing radiation
9. Biological effects of microwave radiations.

Under Defense Atomic Support Agency sponsorship we find:

1. Higher energy neutron radiation effects on mammalian systems
2. Transport of fission products by marine organisms
3. Beta dose from fallout particles
4. SNAP^(b) effects on the ocean environment
5. Dose rate influences on large domestic animals
6. Effects of fallout on simple selected ecosystems.

To provide an even more versatile external radiation source, particularly one for neutrons, the laboratory installed a cyclotron in the late 1960s. The cyclotron was of the azimuthally varying field (AVF) variety, designed to produce extraordinarily high fluxes of 14-MeV neutrons by bombarding appropriate targets with protons or deuterons. Its principal application was to have been to radiobiological research. An initial beam had been developed just as the laboratory was disestablished in November 1969.^(c)

Other studies listed in the many reports from NRDL include more acute radiobiology and much interest in the mechanisms of radiation repair in cells and tissues, as well as the longer-term effects of the moderately high doses, e.g., renal neoplasia, arteriosclerotic changes, biochemical and metabolic alterations, and the growth and reproduction of irradiated animals.

Obviously, the NRDL had become a major laboratory for research in radiobiology, with emphasis on problems of military origin. Of pertinence to aquatic radiobiology were studies on the radiocontamination of marine life. A closed circuit aquarium system was developed, and various species of marine seaweed were cultured therein. Modalities studied besides uptake of radionuclides included possible effects on the sexual cycle of organisms with multiple developmental stages. Ion transport in plants was also studied in order to provide a greater understanding of hazards due to possible broadcast dispersion of radionuclides.

As the space program grew, the laboratory investigated possible inhalation hazards from toxic or radioactive materials potentially released in a space

(a) I am much indebted to Dr. Eugene P. Cooper, Naval Ocean Systems Center, San Diego, California, and a former director of NRDL, for an interview and permission to review in his office many unclassified documents that had been transferred from NRDL.

(b) See chapters 9 and 14.

(c) Details supplied by Eugene Cooper (1983).

vehicle abort or destruct; possible beta dose to tissue from radioactive particle debris was likewise investigated.

Unfortunately, any attempt to delve more deeply into the results of NRDL work than can be learned from the several OPNAV reports is frustrating indeed. Some of the work was published in conventional scientific literature and has been cited in earlier chapters. Large portions remained in NRDL reports. For reasons that will become apparent presently, it appears that there is now no single central source file of NRDL technical reports; at least no one seems to know of such a source. Therefore, this author has had to resort to tapping files of individuals who were at NRDL at one time or another and have kept from a few to many reports. These include, in addition to those already named, Drs. Victor Bond and Stanton Cohn at Brookhaven National Laboratory (BNL) and Dr. Charles Sondhaus at the University of California, Irvine. A partial listing of NRDL reports appeared in the 1959 Congressional hearings on fallout cited in chapter 12. This list, plus a truncated catalog of reports particularly pertinent to the subjects of this book gathered from several sources, is given as note 1 at the end of this chapter.^(a) Many reports that do not concern radionuclides have been passed by for this listing, as have reports and publications that do not involve research. Note 1 constitutes but a minuscule sample of work done over many years by a large and productive staff, but it provides the flavor of their activities bearing on research arising from fallout problems.

Why is it so difficult to obtain NRDL technical reports and to review their contributions in depth?^(b) In the summer of 1968, high Navy and Department of Defense (DoD) echelons decided that NRDL had accomplished its mission and should either go on to something different or shut down. Naturally, the first alternative was chosen, and the laboratory expected to be reoriented as the Navy Nuclear Center. This did not happen. That mission went instead to the Naval Ordnance Laboratory. On April 29, 1969, the NRDL was officially informed that it would be closed as of the end of 1969. The effect was, of course, catastrophic. Even though many of the lower-level personnel received assignments in other Navy laboratories, nearly all of the Division and Section Chiefs sooner or later went elsewhere (Cooper 1969).

Probably the worst feature of the operation was the random dissemination, if not outright destruction, of valuable equipment, including the almost new cyclotron, the laboriously assembled animal colony, and the loss of research records, even for work in progress. True, the records were originally slated to go to other cognizant Navy or other service laboratories. However, when the day of housecleaning arrived, most were arbitrarily consigned to Dempster dumpsters.^(c) Only a few reached other destinations in usable form. This was not one of the U.S. Navy's better performances!

Thus ended abruptly a laboratory that had developed a fine reputation and been graced by scientific and technical directors such as Paul C. Tompkins, Albert Behnke, Eugene Cooper, and Edward Alpen. An unanswered and perhaps unanswerable question is why the Navy, or any military laboratory, required such a widely diversified program in radiobiology when the Atomic

(a) Remember also the citations in chapters 3 and 9.

(b) Much of this discussion rests upon the interview held with Dr. Eugene P. Cooper already mentioned (Cooper 1983), and a draft document he prepared in 1969 (Cooper 1969).

(c) From discussion with Dr. Edward Alpen, March 1984.

Energy Commission (AEC) was at the time supporting handsomely the broadest possible program. Despite the ugly features of implementation of the closing, it may well be that the laboratory had indeed completed its mission. In any event, these occurrences explain why it is hard to find out what was really done except through published papers or by asking former personnel. The information of most pertinence to this book has been discussed or will be in connection with specific subjects.^(a)

B. The University of Tennessee-AEC Agricultural and Research Programs^(b)

This program also began around one of the weapons tests, viz., the Trinity shot at Alamogordo, New Mexico, in 1945. As described in chapter 12, grazing cattle received fallout on their backs, and many developed beta burns. Because of the loss in commercial value, the Army bought up several hundred of the cattle. Sixty of these arrived in Oak Ridge, where they were held for observation of possible long-term effects. When the AEC came into being, a contract was let in 1948 with the Agricultural Research Laboratory of the University of Tennessee. An old school building not far from the main road into Oak Ridge was renovated into a laboratory, surrounding open spaces were fenced off, and there began what was known for many years as the University of Tennessee-Atomic Energy Commission (UT-AEC) Experimental Farm. Financing came part of the time through the Oak Ridge Institute of Nuclear Studies, but the operation remained identified with the University of Tennessee through most of its existence. The dollars came from the AEC.

Cyril L. Comar, a plant physiologist and biochemist, who had already established a reputation for work using radioactive tracers in agricultural research, especially in mineral metabolism (see, for example, Comar 1953a,b), was persuaded to come as director. He proceeded to establish a broad research program whose origins lay in the problems of fallout. He was joined by F. W. Lengemann and R. H. Wasserman and later by John Thompson, Jr., all of whom were also interested in mineral metabolism. These men remained members of the Comar team for over two decades. Several veterinarians worked also at the laboratory. At least two of these established moderately long-term associations with the group, viz., John H. Rust and Bernard F. Trum. Rust went to the University of Chicago in 1959, while Trum went, in the same year, to Massachusetts Institute of Technology (MIT) and Harvard to manage a primate center. Other veterinarians took over to continue the experiments.

(a) The Armed Forces did not abandon radiobiology and nuclear medicine completely at this time. While the above events were occurring at NRDL, the Armed Forces Radiobiology Research Institute (AFRRI) had been established (1961) on the campus of the National Naval Medical Center in Bethesda, Maryland. As described elsewhere, the mission of this laboratory barely began to cover the areas of strength of NRDL. It was concerned at the outset primarily with the effects, particularly on performance, of very high doses of external radiation. It dealt hardly at all with radionuclide problems, and its work cannot, therefore, be considered in any detail herein. It was (and is) well equipped with irradiators, a research reactor, and it has sponsored good programs in basic molecular biology. It is still quite active and has a broad program.

(b) I am indebted to Dr. T. R. Noonan for providing early progress reports, a complete list of publications, and many reprints of work at this laboratory.

Let us look first at what became of the Alamogordo animals. Of the sixty Hereford cattle (forty-one cows, eighteen steers, and one bull),^(a) all but eleven had to be destroyed in 1951 because of anaplasmosis, a malady quite unrelated to radiation exposure. Despite this regrettable loss of statistical strength, the story continues until 1964 when the last cow died. By this time, Comar had gone to Cornell University (see next section), but a competent veterinarian (D. G. Brown) and colleagues carried on. They described the long-term effects of the fallout on these animals in 1966, over twenty years after the contamination event (Brown, Reynolds, and Johnson 1966).^(b)

There were ninety-four calves brought to weaning from these eleven cows beginning in 1948 (out of 114 possible "breeding years"). In addition, two calves were born dead and four that appeared normal at birth died before weaning. Evidently, this performance is not unusual in such herds.

Hemograms and other clinical tests were essentially negative. The most significant damage from irradiation was associated with the areas of the beta burns, i.e., "hyperkeratosis in the form of plaques and cutaneous horns on the skin of the dorsum" (Brown, Reynolds, and Johnson 1966). Three of the cows that survived fifteen or more years after receiving fallout on the skin developed squamous cell carcinoma at the site of the irradiation lesions. The radiation doses were estimated at 150 R of penetrating and 37,000 rad of beta radiation to the skin surface.

The lesions did not seem to affect breeding efficiency or relative fertility. Indeed, over the period before the anaplasmosis epidemic, the entire herd's performance was slightly ahead of the controls. This is illustrated in table 13.1, taken from an M.S. thesis by J. M. Bird at the University of Tennessee quoted by Brown, Reynolds, and Johnson (1966).

TABLE 13.1. Breeding Efficiency and Relative Fertility of Cows Exposed to Radioactive Fallout in 1945 During the Period 1948-1951*

A picture of the last surviving cow from the Alamogordo herd is shown as figure 13.1.

- (a) There were also seventy-four controls of local origin raised with the Alamogordo herd.
 (b) This work is obviously not experimental, but it needs to be described as part of the laboratory's heritage.

FIGURE 13.1. Alamogordo Cow Number 52, the last surviving member of the herd accidentally exposed to fallout from the Trinity shot in July 1945, and calf. She produced sixteen consecutive calves, all apparently normal. Note the areas of lighter color on the back, site of the beta burns. In some animals, these areas became squamous cell carcinomas, but not in the majority despite a high beta radiation dose. Photograph taken in 1964. (Courtesy of Thomas R. Noonan, Comparative Animal Research Laboratory, Oak Ridge, Tennessee.)

The more strictly research enterprises at UT-AEC Farm concerned radioisotope metabolism. Even before the official facilities were ready, arrangements were made for Dr. Comar and his early colleagues, S. L. Hood and S. L. Hansard, to conduct preliminary studies on calcium metabolism using ^{45}Ca at the Special Training Division of the Oak Ridge Institute for Nuclear Studies. By 1949, nine projects were in the planning stages and two or three were started:

1. Bomb radiation effects on farm animals
2. Fission product metabolism in animals
3. Absorption and distribution of radiocalcium
4. Interrelationships of radiocalcium metabolism with other minerals, vitamins, and hormones
5. Radiation effects on reproductive function in farm animals
6. Radioisotopes in poultry nutrition
7. Radioisotopes in the physiology of milk secretion
8. Behavior and fate of radiocalcium after incorporation in soil
9. Relation of soil types to availability of nutrients.

By 1951, all of these studies had been activated, and a tenth project, "External Radiation Studies in Large Animals," had been added. For the latter, a large animal exposure field was developed using a multicurie radioisotope source of gamma radiation.

By far the best known of the pure research enterprises concerned the metabolism of pairs of elements, e.g., strontium/calcium (see chapter 12 for discussion of the Sunshine Unit based on this ratio) and the presence and reasons for discrimination between such pairs of elements. Since this work involved fundamental concepts that apply to all of the metabolic research stimulated by the fallout problems in the several laboratories, we will discuss it as an entity in section III.

There was also much work on the behavior of strontium, cesium, and other radionuclides in fallout in a variety of farm animals. Important results came out of the studies to determine the effects of various factors both in the environment and within the animals, including transplacental transfer of important radionuclides not in fallout (Hansard 1969). The program confirmed in large measure the basic phenomena seen in small laboratory animals, as described in chapter 8. Some fairly heroic techniques were developed, e.g., to separate urine from feces in the cow, as shown in figure 13.2.

FIGURE 13.2. Arrangement for separate collection of urine and feces from the dairy cow; the large animal version of a metabolism cage, used at UT-AEC Farm. The laboratory also designed a metabolism unit for radioisotope balance studies with dogs (see Hansard 1953). (Courtesy of John Thompson, Jr., now at Cornell University, from his collection of Oak Ridge pictures.)

The basic research on mineral metabolism involved much work with bone. The laboratory developed a strong capability with autoradiography with particular help from William E. Lotz, who was Cyril Comar's first Ph.D. student at the University of Tennessee (1950), and from George A. Boyd and John C. Gallimore, who came to Oak Ridge from the University of Rochester (Comar, Lotz and Boyd 1952; Lotz, Gallimore, and Boyd, 1952; Lotz and Johnston, 1953).^(a) The work utilized such well-established tracers for mineral metabolism as ^{45}Ca and ^{32}P , in addition to the radionuclides in fallout. Both animal and plant materials were utilized.

The work at Oak Ridge continued for many more years after the departure of Comar and some of his colleagues (see next section). Key staff members were D. G. Brown, M. C. Bell, J. K. Miller, F. R. Mraz, R. A. Reynolds, G. E. Spalding, and others. S. L. Hansard, who had been with the laboratory from the beginning, assumed many of the administrative duties of scientific direction and continued his scientific work. In due course, the laboratory became the Comparative Animal Research Laboratory (CARL) of the University of Tennessee and Department of Energy (DOE). Among other personnel changes, Dr. Thomas Noonan, who spent many years at the Rochester Project, took over as research director. The laboratory placed less emphasis on the radioisotopes in fallout (obviously the problems had become less urgent) but kept on with more generalized tracers and a few continuing enterprises such as iodine metabolism. Also, facilities were installed to work with the transuranic elements whose importance had grown over the years. There was more research emphasis, relatively, on external radiation effects. The laboratory participated very actively in efforts of the university, the state, and the U.S. Office of Civil Defense and its successor agency, the Defense Civil Preparedness Agency, to inform the agricultural community of the possible effects of fallout on farm animals and crops and possible measures to take in the event of contamination.

Not coming under headings to be discussed in sections III and IV is work combining exposure to radionuclides and external gamma radiation (e.g., Bell, Lowrey, and Winthrow 1967), the toxicity of very high levels of certain radionuclides on avian embryos (Mraz, Wright, and Ferguson 1964; Wright and Mraz 1965; Mraz 1966, 1969), embryonic uptake of calcium and strontium (Mraz 1970), and the effect of dietary strontium on reproductive performance in poultry (Mraz, Wright, and Ferguson 1967).

Dr. Noonan retired in due course, and CARL became something of a holding operation. Indeed, it seemed to be headed toward termination. Instead the laboratory was consolidated into the Medical Division of the Oak Ridge Institute of Nuclear Studies (ORINS)—Oak Ridge Associated Universities (ORAU) under the temporary direction of Dr. Clarence Lushbaugh. Dr. William Burr, formerly director of the Division of Biomedical and Environmental Research at the DOE Headquarters, has agreed to direct the former CARL program. While the original mission may be considered completed, the important metabolic work will probably be combined with other work of ORAU and continued under Dr. Burr's capable direction.

(a) Lotz collaborated with Comar and others at the UT-AEC Farm on several other projects. He also worked in the Medical Division of the Oak Ridge Institute of Nuclear Studies before going to Washington to the AEC's Division of Biology and Medicine (see chapter 9).

Research at the UT-AEC Farm provided some very basic concepts as well as confirmation in large animals, in plants, and in other agricultural materials of the findings described for laboratory animals in chapter 8. Laboratory research and practical agricultural enterprises had to compete for manpower and funds. There were over 650 publications up to 1977. A list of selected publications pertinent to this chapter, in addition to those cited specifically in the text, along with a few others is given as note 2 at the end of this chapter.

C. Cornell University^(a)

It must have been 1956 or earlier that plans were made to organize a radiobiology program at the New York State College of Veterinary Medicine operated by Cornell University. It was cast very much in the mold of Cyril Comar's program at Oak Ridge, and in 1957 Comar transferred his activities from Oak Ridge to Ithaca. Wasserman went to Cornell shortly thereafter. Lengemann came on a visiting basis in the summer of 1958 and permanently in 1959. John Thompson, Jr., also transferred from Oak Ridge. There were facilities on the campus, and a separate farm facility was built away from the campus, which incorporated a multicurie gamma source for irradiation of animals of all descriptions. The operation was designated the Laboratory of Radiation Biology and was supported by the AEC, the Department of Agriculture (USDA), the Defense Atomic Support Agency, and the U.S. Public Health Service (PHS). It began as part of the Department of Physiology of the Veterinary School. Before long, it grew into departmental status in its own right and was designated the Department of Physical Biology.

We do not have any written record of the *raison d'être* for developing another laboratory with a mission so similar to the UT-AEC farm or the willingness of the AEC to underwrite two such similar enterprises. We can make some guesses however. The Cornell enterprise began near the height of the fallout controversy. Perhaps the AEC desired an agriculturally oriented laboratory more distant from one of its prime installations. Perhaps, particularly since the work involved much need for collaboration with physiologists, pathologists, nutritionists, biochemists, and so forth, the potential for in-situ liaison on a university campus weighed heavily. (The University of Tennessee campus was about thirty miles from the Oak Ridge farm.) The chances for developing a strong academic department were better at Cornell. The development of educational programs would be simpler at Cornell. Indeed, it turned out that the Cornell Department of Physical Biology became a center for graduate education and for summer and academic year institutes in radiobiology. Alison P. Casarett, who migrated to Cornell from Rochester and who wrote a well-known textbook, *Radiation Biology* (Casarett 1968), was largely responsible for the success of these many training and education functions.

The scientific program was naturally very similar to what had been done at the UT-AEC Farm at Oak Ridge, minus, of course, the Alamogordo cattle. A listing follows of the experimental studies under way in a typical year (1964-1965) when the fallout work was a prime stimulus. It is taken from the Annual

(a) I am indebted to Drs. A. P. Casarett, F. Lengemann, and J. Thompson, Jr., for information on the development of the Laboratory and its programs. Unfortunately, the written record is very sparse.

Progress Report, Cornell University Department of Physical Biology, 1964-1965 (courtesy of Drs. F. Lengemann and A. P. Casarett, Cornell University).

A. Phase I—Fission Product Metabolism and Response in Laboratory and Domestic Animals

1. Retention of Strontium as a Function of Age in the Beagle
2. Incorporation of Strontium and Calcium into Human Chromosomes
3. The Transport of Calcium, Strontium and Barium Across Rabbit Duodenum *In Vitro*
4. Vitamin D Enhancement of the Unidirectional Fluxes of Calcium Across Rachitic Chick Ileum and Rat Duodenum
5. Predicting the Total Projected Intake by Man of Radioiodine from Milk
 - I. The Situation Where No Countermeasures are Taken
 - II. The Situation Where Countermeasures are Employed
6. Predicting the Total Intake of Radioiodine by Humans Consuming Goat's Milk
7. The Turnover of Cesium in Rats as Affected by Temperature, Water Consumption, Cellulose Content of Diet, and Hypothyroidism
8. Urine/Diet Studies
9. Genetic Studies on Cell Wall Mutants of *Staphylococcus aureus*
10. Erythrocyte Loss and Restitution in Ovine Haemonchosis

B. Phase II—Planning Study for Evaluation of Radioactive Contamination of the Food Chain

1. Fluid Milk Consumption: Variability and Relationship to Radionuclide Intake
2. Nutritional Aspects of Food Chain Contamination
3. Sr^{90} and Cs^{137} Studies in Selected Vegetable Crops
4. Radionuclide Prediction Studies
5. World Fallout Data Assessment and Summaries

Later, the program on the campus broadened to include aspects of neurobiology. Some of them were oriented toward radiation effects, especially measures of performance following high doses of external radiation and also possible subtle behavioral changes at lower doses, but there was much basic neurobiology. The connection to the original problems of radionuclide metabolism continued, nevertheless, with work on environmental transport, membrane transport of alkaline earths and the mechanisms involved, strontium metabolism and secretion in milk. These included a modicum of work on human subjects for tracer studies, secretion of strontium in human milk, etc.

Work pertaining to the many aspects, both laboratory and environmental, of atomic energy and agriculture carried out at Cornell is cited, in part, in the list of selected publications from Cornell shown as note 3 at the end of this chapter. There was a very useful annotated bibliography of strontium and calcium metabolism by Wasserman and Comar published by the USDA (Wasserman and Comar 1961).

In early 1975, Comar moved back to California, where he had been educated, as director of the Environmental Assessment Department of the Electric Power Research Institute in Palo Alto. There he gradually applied the talents and methodology developed originally around the problems of fallout to those of other forms of energy generation, particularly coal. At Cornell, Lengemann, Johnson, Wasserman, and others kept the radionuclide and mineral metabolism program going; Casarett and others continued to work with external radiation

and the education program until Casarett entered the administrative echelons as dean of graduate studies and later vice provost and provost. However, the department eventually lost its identity. After some intermediary stages, the work is now back in the Department of Physiology of the Veterinary College.

It is probably fair to say that the motivation for current research at Cornell is no longer the problems of fallout; yet they stuck very close to the basic program for many years and followed through at the mechanistic level to a very satisfying degree. We will review some of the specifics in later sections.

D. University of California at Davis, Radiobiology Laboratory and Later Laboratory of Energy Related Health Research^(a)

This project qualified as one of the postwar "King-Sized Experiments" and has had implications for the entire field of radionuclide metabolism. Thus, its origin and the development of its programs were described in chapter 8. (See "Davis Beagle Project.") The primary radionuclide was ^{90}Sr , with ^{226}Ra as a tie-in to both the Utah project and experience in humans. The primary route of administration was via the diet. The milieu was again a School of Veterinary Medicine, and there were strong ties to agricultural research. For these reasons, most of the results of the Davis enterprise can be regarded as related directly to the problems of fallout and should be described here, even though the development began shortly before fallout problems reached compelling proportions.

The personnel, the complete plan of the main experiment including the dosage levels, and a few details of the protocols are given in chapter 8. In section IV of this chapter, we will review, under "Strontium," the primary thrust of the results. It should be noted that the dosage regimen was rather different from many of the other experiments discussed thus far in this chapter. Besides utilizing the oral route, the intake was more or less continuous over long periods. It thus resembled the large experiment with iodine in sheep done at Hanford (chapter 8). A basic question was not only how intake via the diet might influence metabolism and effects, but how more or less continuous intake might modify these as compared to a single injection, as in the Utah experiment. As we will see, there were significant modifications of both metabolism and effects.

There were many ancillary experiments directed at mechanisms, species comparisons, isotopes other than strontium, such as iodine, effects in pregnant and fetal animals, etc. These too will appear largely in section IV. The last animals from the main experiment are approaching the end of their expected life spans. Emphasis on mechanistic aspects has been expanding. Also, the base of the work has gone far beyond radionuclides of fallout, even nuclear energy to other forms of energy generation (hence, the name change to "Laboratory of Energy Related Health Research").^(b) It remains to be seen whether or not completion of the original experimental protocol will lead to termination of this laboratory as an entity or if it can proceed on the new tracks it has laid, particularly now that the culmination of many hints regarding mechanisms gathered during the days of confining pragmatic operations are beginning to show signs of coming to fruition.

(a) I am indebted to Dr. Marvin Goldman for an overview of the work at this laboratory, an interview, and background literature.

(b) An extensive aerosol and inhalation toxicology laboratory has been developed as part of the Davis enterprise.

E. Southwestern Radiological Health Laboratory^(a)

In chapter 12, we saw the development of offsite surveillance activity, particularly for the Nevada Test Site (NTS), under the aegis of the PHS. A small group of PHS officers, led by Oliver Placak, spearheaded this activity. In 1954, with the signing of an official Memorandum of Understanding with AEC, a small staff of regular commissioned PHS officers was permanently stationed in Nevada to head up the program that had been operated largely by assigning Reserve Officers on temporary duty. In 1959, with the fallout controversy heating up still further, the PHS's new Division of Radiological Health established the first of the three regional radiological health facilities, this one in Las Vegas. They called it the Southwestern Radiological Health Laboratory (SWRHL).^(b)

While the nucleus was the radiological safety program, research projects gradually developed, some of which concerned methods for removal of radioisotopes, particularly strontium, from milk and other foods (chapter 12). Early there was much work on development of instrumentation and methods and field-type research around the indigenous animals on the test sites. In 1963, an experimental farm was begun on a thirty-acre plot on the NTS. Full facilities were completed there in 1966. There was a beef herd, mostly kept on the range, and a milking herd of dairy cows that was kept in corrals. The operation continued until 1979. Crops were planted and irrigated under such conditions that simulated fallout from controlled releases could impinge upon the soil and foliage. Major emphasis was placed upon the transport of radioiodine through the soil-forage-cow-milk chain. The agronomic aspects were described by Daley and Smith (1969).

Pictures of the laboratory buildings in Las Vegas, the farm at NTS from near and far, and the SWRHL version of a bovine metabolism cage are shown in figure 13.3A, B, C, and D.

FIGURE 13.3A. Southwestern Radiological Health Laboratory, Las Vegas, Nevada. (Courtesy of U.S. Department of Health, Education and Welfare 1966.)

(a) I am indebted to Mrs. Geneva Douglas, former director of this laboratory's Information Services for capsule histories, a complete list of publications, selected reprints of the published work, and for a review of the section. Also, Dr. Melvin Carter, the laboratory's second director, provided much information, an interview, and several pictures.

(b) The others were the Northeastern Radiological Health Laboratory in Winchester, Massachusetts, and the Southeastern Radiological Health Laboratory in Montgomery, Alabama. We have already mentioned work from these installations.

FIGURE 13.3B. (Right) Moderately close-up view of the Southwestern Radiological Health Laboratory on the Nevada Test Site. The dairy herd was kept in corrals in the foreground, the crops potentially exposed to fallout were grown on an irrigated field in the near distance. Not shown is the beef herd that was on more open range. (Courtesy of Geneva S. Douglas, U.S. Environmental Protection Agency, Las Vegas.)

FIGURE 13.3C. (Left) Further out view of the Southwestern Radiological Health Laboratory Farm on the Nevada Test Site. The irrigated crops grown for forage are on the dark rectangle in the center. (Courtesy of Geneva S. Douglas, U.S. Environmental Protection Agency, Las Vegas.)

FIGURE 13.3D. (Right) The Public Health Service version of a bovine metabolism cage as installed at the large-animal farm at the Nevada Test Site. These animals were fed in part with forage grown in the area depicted in figure 13.3C. (Courtesy of Geneva S. Douglas, U.S. Environmental Protection Agency, Las Vegas.)

It was possible to introduce variations in the soil and other conditions, even to prepare and release on the crops aerosols tagged with ^{131}I and determine the passage of the isotope from such a source through the food chain (see, for example, Stanley, Black, and Barth 1969; Douglas, Black, and Barth 1971; James et al. 1970; Mason, Black, and Barth 1971; Black et al. 1971).

In another approach, hay bales were placed from thirty to fifty miles from ground zero of a nuclear burst, and the hay, after recovery, was fed to dairy cows at the farm as a controlled ingestion experiment (Black, McNelis, and Bretthauer 1972). In other cases, the cows were exposed directly to the effluent cloud (Black et al. 1971). The results of these and related experiments will be viewed in combination with other research in section IV.

A novel approach to determining the radionuclide composition of the diet ingested by the cattle was the preparation of rumen-fistulated steers. (a) The indwelling tube was capped with a lid like a jar. This indwelling hardware seemed to cause the animals no discomfort. One member of the beef herd, "Big Sam," seemed very proud of his special device and willingly showed it at special events, including county fairs. A picture of "Big Sam" is given as figure 13.4.

FIGURE 13.4. "Big Sam," one of several rumen-fistulated steers in the beef herd kept at the Southwestern Radiological Health Laboratory Area of the Nevada Test Site. The cap of the fistula is easily removed to provide samples of the range diet and, on analysis, its radionuclide content. It is assumed that the diet of the rumen-fistulated steers imitates that of the entire herd. Such animals have been on the range for many years. (From "Environmental Information," U.S. Environmental Protection Agency, June 1979, courtesy of Geneva Douglas.)

By 1966, SWRHL had grown to a staff of 220 and had five buildings on the campus of Nevada Southern University (now University of Nevada at Las Vegas; see figure 13.3A). These facilities were provided through the U.S. Congress and the state of Nevada and leased to the PHS. In addition to excellent laboratories for radiochemical work, the facility was well provided with whole-body counters for people and animals and much paraphernalia for environmental sampling. At NTS, the special facilities pictured in figure 13.3B, C, and D allowed work under field conditions at higher levels of radioactivity.

In 1970, as we know, the new U.S. Environmental Protection Agency (EPA) took over SWRHL from the PHS. There has been a gradual transfer of the

(a) A surgical opening made in the animal's side provided easy access to the rumen so that the contents of the forestomach could be sampled.

research and monitoring to nonradioactive substances. There was some collaboration with the Nevada Applied Ecology Group of DOE (see chapter 14) on problems of residual contamination of NTS with long-lived transuranics. The program has deemphasized research somewhat in recent years, but the monitoring and environmental assessment capabilities have remained strong.

In the formative years (1953–October 1967), SWRHL was directed by Oliver Placak, who was ubiquitous around the Nevada tests. During the period of most rapid research growth and the period of transfer to EPA, the director was Melvin W. Carter (March 1968–August 1972), who is now at the Georgia Institute of Technology in Atlanta. He was followed by Delbert S. Barth (September 1972–September 1976), some of whose work we have already cited. There was new experimental work on individual radionuclides given to cattle and a gradual shift of the monitoring programs to contemporary problems such as tritium, krypton, uranium in mill tailing, etc., but the iodine work continued more or less without serious interruption.

Other activities at SWRHL concerned some of the special events reserved for discussion in chapter 14. On balance, it can be said that SWRHL never lost its roots or commitment to environmental monitoring and research on environmental transfer phenomena and that it managed a fine blending of an occasional pure research venture in a milieu of assessment and monitoring.

F. Other U.S. Public Health Service Laboratories

In chapter 10, we reviewed work done at the PHS laboratory in Montgomery, Alabama, on radiokrypton and by a PHS officer (Cahill) working at Rochester and later at the EPA's Research Triangle installation in North Carolina on tritium. These researchers were stimulated in part by the problems of fallout, in part by general problems of environmental contamination with radionuclides.

A fairly vigorous program was developed on radionuclide metabolism and effects at the Robert A. Taft Center in Cincinnati. This was called the Radionuclide Toxicology Laboratory and was headed by a PHS officer, Jerry F. Stara. It emphasized strontium in cats, and a fairly extensive outdoor breeding colony for cats was developed. However, there was work also on iodine and the usefulness of various pharmaceuticals for repressing uptake of radionuclides from the gut (chapter 19).

In 1968, the PHS decided to move the Radionuclide Toxicology Laboratory from Cincinnati to the Twinbrook Laboratory in Rockville, Maryland. This may have been partly because the Cincinnati laboratory was primarily concerned with engineering, particularly industrial hygiene engineering. The work continued for many years but at diminished intensity. Publications, particularly on long-term pathological effects in the cat, appeared as late as 1972. We will review the results of PHS research with strontium and iodine in section IV.

There was some experimental work from the Robert A. Taft Center on experimental uptake of ^{85}Sr by freshwater organisms (Brüings 1965). This was a factorial study of the effects of varying the concentrations of calcium, magnesium, sodium, and potassium on the uptake of ^{85}Sr by small bluegills in laboratory aquaria. Of the four cations used, only calcium had a significant effect. There was also a study in a small pond to determine total uptake of the strontium in a natural environment. The amounts in the organisms never exceeded 0.5% of the amount added, and this was related to the age of the fish. Only about a quarter

of the added "soluble" ^{85}Sr remained in the dissolved phase over an eighty-day experimental period.

We are already aware of the important part played by physicians from the PHS in the investigation of possible thyroid pathology in the Utah and Nevada residents exposed to fallout from NTS (chapter 12). Much of this was coordinated by the Radiation Bioeffects Program in Rockville. Arthur H. Wolff was chief of the program until the midsixties. He was replaced by William A. Mills when Wolff was asked to spearhead a new activity concerning consumer products. Norman Telles headed the radiation oncology and pathology effort, which involved both laboratory and epidemiologic approaches.^(a)

Overviews of the PHS program, variably called "Radiological Health Research" or "Radiation Bioeffects," can be seen in annual summary reports (PHS 1965-1966, 1967, 1968, 1970).^(b)

II. Special Programs at Established Laboratories

While the contrast between the efforts depicted in section I and those to be discussed in this section is largely a matter of context and *raison d'être*, and the actual results can be discussed more or less in unison, it is convenient to describe separately those programs that were added to ongoing work in well-established laboratories to attack some phase of the fallout problem. Included are only those entities that could be regarded nominally as "special programs," i.e., that probably would not have been undertaken without the stimulus of the problems of weapons-testing fallout. They, of course, tie closely to research activities in the same laboratories reviewed in earlier chapters or to be considered in chapters 19 and 20. General descriptions of the work appear in this section.

A. Argonne National Laboratory

The chief addition to the Argonne National Laboratory (ANL) program that we might attribute to fallout problems was increased emphasis on the effects of chronic administration, particularly of strontium isotopes. The experiments with mice for determining toxicity ratios and their results were taken up in detail in chapter 8. There was further work with mice and studies with beagles. Both were carried out by Miriam Finkel and her colleagues. Probably one of the most

(a) Work with radionuclides at the PHS laboratories that was not stimulated by or related to problems of fallout concerned naturally occurring heavy elements, such as polonium, radiolead, and some of the other components of the radon, radon-daughter series, and also Thorotrast. This work was headed by R. L. Blanchard with collaboration from S. C. Black among others. There were, of course, many PHS research programs concerned with external radiation sources. The most extensive was the Collaborative Radiological Health Laboratory located on the campus of Colorado State University at Fort Collins, which involved use of a barrier-maintained colony of beagles. To the extent that it focused on long-term effects of radiation, it could be said to have a bearing on the problems of fallout. The National Institutes of Health also had a program concerned largely with external radiation sources and basic radiobiology.

(b) I am indebted to Dr. John Villforth, long-time director of the PHS and later Food and Drug Administration activities in the field of radiological health, for supplying copies of these reports and other publications.

germane summaries for our present purpose is the one at the Symposium on Radioisotopes in the Biosphere held in Minneapolis (Finkel, Biskis, and Bergstrand 1960). The work with dogs was summarized by Finkel and colleagues at the Davis symposium on strontium (Finkel et al. 1972).

Finkel has long held the idea that initially high dose rates of low linear-energy-transfer (LET) radiations such as those from ^{90}Sr - ^{90}Y were more effective than constant low dose rates in producing tumors for the same total absorbed dose. Thus, she expected greater effectiveness of single intakes with their high initial radiation dose rate compared to a more constant intake with lower dose rates even at comparable total doses. Experiments were carried out with mice to test this hypothesis. Other experiments involved injecting beagles five times a week for one year for comparison with a single injection and thus for comparison with the results of the Utah beagle experiment. This was not a large program compared to the major beagle programs, but it served as a link between the extensive work at ANL with mice and the large dog experiments elsewhere. There was also an experiment in which mice were maintained on diets containing a constant ^{90}Sr -to-stable-calcium ratio throughout life. Each of these will be reviewed, as required beyond what was discussed in chapter 8, in section IV of this chapter.

During the active phases of fallout work, Finkel appraised the situation in a review prepared for *Science* (Finkel 1958). The potential danger to humans was evaluated on the basis of the animal experiments. She extrapolated the dose-response curves from these experiments and the results to date of the comparative toxicity work then in progress. She concluded that ^{90}Sr may be seven to fourteen times as toxic in humans as in mice. Nevertheless, the data led her to conclude that there was a very small probability that there was or could be a linear no-threshold dose-response relationship to ^{90}Sr in humans. She proposed a minimum effective dose for ^{90}Sr in humans of 6 to 15 μCi . Comparison of this to the calculated body burdens from fallout (on the order of 0.0002 μCi and a predicted steady-state value of about 0.02 μCi) led Finkel to conclude that "the present contamination with ^{90}Sr from fallout is so much lower than any of these levels that it is extremely unlikely to induce even one bone tumor or one case of leukemia" (Finkel 1958, p. 641).

This conclusion drew fire from many of the participants in the fallout polemic then in progress and came into discussions at the 1959 Congressional hearings (see U.S. Congress 1959 in chapter 12). Linus Pauling and colleague Barclay Kamb at Cal Tech prepared a detailed statistical analysis of the data Finkel used (Kamb and Pauling 1959). It was published in the *Proceedings of the National Academy of Sciences* and reproduced in the record of the Congressional hearings.

Briefly, Kamb and Pauling concluded that there were far too few animals in the experiment to allow any conclusions regarding linearity or nonlinearity of the dose-response curves. Indeed, they calculated that to establish statistical validity for one choice over another at 90% confidence would require over a billion mice in each dosage group.^(a)

(a) This author can see how such a large number would be needed to validate the points at levels such as 0.0002 μCi but is puzzled that the required group size would not decrease as the dose increased. Some of the doses in Finkel's experiment were rather high.

The argument is directed as much at the life-span shortening data as at the production of osteogenic sarcomas. It cites the fact that other functions, e.g., the Gompertz function, which is essentially linear, could fit the data quite well, and they devised some equations of their own. They presented several figures in which equations they derived fit Finkel's experimental points satisfactorily. They conclude that the only prudent course is to assume linearity and characterize Finkel's conclusion, quoted above, as "not justified." (a)

Dr. Finkel's conclusions were announced in the press. So were Dr. Pauling's criticisms. It is stated that Finkel wrote a reply to Pauling's "letter to the editor" of the *New York Times* (November 16, 1958) on November 30, 1958. Unfortunately, I have not been able to view a copy of this reply but can assure the reader that it was not a capitulation. There never can be a direct experiment that can establish dose-effect relationships in these very low dose realms. Therefore, opinions can legitimately differ. (b)

B. University of California at Berkeley

As the seat of the original biomedical work on fission products (chapter 6), Berkeley hardly needed to mount a special program to make significant contributions to research bearing on fallout. Yet a few items need description here.

First it should be pointed out that the very first paper on the secretion of radiostrontium in cow's milk came from prewar work at Berkeley. Erf and Pechier (1940) used ^{89}Sr as a surrogate for ^{45}Ca because they had difficulty obtaining the latter in sufficient yield from the cyclotron and because of the difficulty in measuring the very soft beta particle of ^{45}Ca . They injected two cows intravenously and measured the secretion of ^{89}Sr in milk for 102 hr. It was about 7.9% and 11% of the dose, respectively.

An experiment with ^{90}Sr in the rhesus monkey was begun quite early by Pat Durbin (chapter 8) with encouragement from Joe Hamilton. The experiment contained forty adolescent and adult female and male rhesus monkeys aged two to twelve years at the start of the experiment. They received from 0.5 to 20 μCi $^{90}\text{Sr}/\text{kg}$ (3.5 to 168 μCi per animal) and, except for two short-term animals that received 50 $\mu\text{Ci}/\text{kg}$, were followed for up to twenty years after the single injection (intravenous, intraperitoneal, or intramuscular). Despite what appear to be moderately high levels of injected radionuclides, no biological effects were detected. Thus, the experiment became largely a metabolism study. It provided important data on retention of ^{90}Sr in a primate over a twenty-year span of observations. These will be discussed under strontium in part IV of this chapter. A summary of the experiment was provided by Durbin and colleagues at the Third International Congress of the International Radiation Protection Association held in 1973 (Durbin et al. 1974). They concluded that rhesus

(a) Does this sound familiar? It should. The polemic is still going on even though the radiation protection fraternity has largely adopted the linear hypothesis or varieties thereof (chapter 16) as prudent for planning purposes.

(b) It could be argued that this discussion belongs in chapter 12, along with the general discussions that took place at the Congressional hearings. It is placed here because the conclusions were drawn directly from specific research data, not a generalized statement such as "the amounts found were well below established maximum permissible exposures." Also, the response from Pauling bore specifically on these research data and was a sophisticated research contribution in its own right.

monkeys of varying ages provide a suitable model to evaluate the long-term metabolism of the alkaline earth elements in larger species, including humans.

There was also work at Berkeley, but not in the Radiation Laboratory, on the uptake of fission products by plants.

C. Brookhaven National Laboratory

The key role played by BNL in the care and study of the Marshall Island inhabitants was described in chapter 12. Stanton H. Cohn set up the whole-body counting facility at Brookhaven soon after he transferred from NRDL and has used it for many years both for measurement of radionuclides from fallout in the general population and in the Marshallese and for experimental work involving both humans and animals. His years at NRDL could not help but sustain his interest in fallout problems, while his general interest in mineral metabolism has led to much basic work on bone.^(a)

Typical experiments of the 1960s, when the fallout problems were of overwhelming importance, are:

1. effect of aging and x-irradiation on the kinetics of skeletal metabolism in the rat (Cohn 1961);
2. diet-induced changes in the exchange and accretion of radiostrontium by rat skeleton (Cohn, Nobel, and Sobel 1961);
3. turnover of ^{85}Sr in man as determined by whole-body counting (Cohn et al. 1962b);
4. influence of dietary stable strontium and calcium on the turnover of bone-fixed ^{85}Sr in man (Cohn et al. 1962a);
5. comparative kinetics of ^{47}Ca and ^{85}Sr in man (Cohn et al. 1963a);
6. study of the uptake and transfer of fallout ^{131}I in pregnant women (Cohn and Gusmano 1963);
7. long-term ^{137}Cs turnover in man as measured by a whole-body counter (Cohn et al. 1963b);
8. cesium-137 metabolism in man (Rosoff, Cohn, and Spencer 1963);
9. effect of magnesium on the uptake and retention of radioactive strontium (Clark et al. 1964);
10. metabolism of ^{65}Zn in man (Spencer et al. 1965);
11. decrement in radiostrontium retention following stable strontium prefeeding in the growing rat (Teree, Gusmano, and Cohn 1965);
12. strontium and calcium skeletal discrimination determined by compartmental analysis (Cohn et al. 1966);
13. kinetics of strontium and calcium metabolism in the rat (Cohn and Gusmano 1967);
14. evaluation of the parameters of strontium metabolism in the rat as a function of age (Gusmano et al. 1968).

Gradually, the research turned to neutron activation analysis, studies of osteoporosis and other bone diseases, and studies of calcium metabolism.^(b)

(a) In chapter 9 we described Cohn's work in the inhalation field, including a study with ^{85}Kr at BNL.

(b) The H. Spencer in the citations above is Dr. Herta Spencer, first at Montefiore Hospital in New York and later at Hines Veterans Hospital in Illinois. Dr. Spencer ran an important metabolism ward for studies on man and collaborated extensively with Dr. Cohn. We discuss her work in some detail in chapter 19.

Some of the work cited above will be woven into our discussions of strontium and cesium in section IV. There can be no doubt that experience with the fallout problems determined the course of much basic research at Brookhaven and directed the career of Stanton Cohn as the Marshallese problems had directed Conard and others (chapter 12). Indeed, Cohn stated in a personal interview, "My specialty is calcium because of fission products and especially strontium" (Cohn 1982).

The resemblance between these activities and those of Comar's group (UT-AEC Farm and Cornell University) is obvious. The emphasis in the BNL studies was, of course, much more on man.

D. Battelle, Pacific Northwest Laboratories (Hanford)

We saw some of the measurement activities that were carried out at Hanford in Richland, Washington, and around the test sites by Hanford personnel in chapter 12. Since Hanford was the original installation deeply involved with problems of environmental contamination (chapter 11), it is not easy to earmark specific research there as being "stimulated" by the fallout problems. There were no projects overtly designated as having been so stimulated. Nevertheless, pertinence to fallout problems is obvious for some of them, and many have pertinence whether or not conceived for the purpose. Thus, the large experiment with iodine in sheep, which obviously was begun well before fallout had become a cause célèbre, had its origin in the finding of local contamination as discussed in chapter 8; it will not be repeated here. On the other hand, a large experiment with strontium in miniature swine, begun slightly later, was only touched upon in chapter 8 and was clearly related to fallout problems. Also, work at Hanford on strontium in rats was not discussed at all in chapter 8. This, plus work on the behavior of pairs of elements, nutritional considerations in the metabolism of strontium, work on cesium, and a large amount of field and laboratory work with plants, have all been reserved for present considerations.^(a)

We present below a capsule summary of the nature of the enterprises at Pacific Northwest Laboratory (PNL) and a few details so that the contributions of the Hanford group can be seen uncluttered by the details of the results of other work.

1. The Experiment with Strontium-90 in Swine

The development of the miniature swine used in this experiment is described briefly in chapter 8. The enterprise was a feeding experiment involving over eight hundred swine. The levels, fed individually with the morning ration of feed, were 1, 5, 25, 125, 625, and 3,100 μCi per day. These dosage levels were chosen to fit approximately the expected body burdens in the Argonne and Utah dogs that were receiving strontium intravenously and the large feeding experiment at the University of California at Davis. It extended over three generations. The first generation entered the experiment at nine months of age. The second and third generations were exposed throughout life, beginning in

(a) The enormous efforts at PNL on inhaled radioisotopes are described in chapters 9 and 10. These involve many of the fission products as well as transuranic elements. It was considered advisable to review all of the inhalation toxicology (pulmonary radiotoxicology) together in those two chapters; it will not be repeated here. The work includes strontium, ruthenium, and iodine in particular.

utero. Thus, there were many resemblances in protocol between this experiment and the one with iodine in sheep described in chapter 8.

The general protocol is outlined in figure 13.5, taken from a moderately early report by McClellan et al. (1962). In addition to the swine listed in the figure, there were 270 untreated animals that served as controls. Results are discussed in section IV of this chapter.

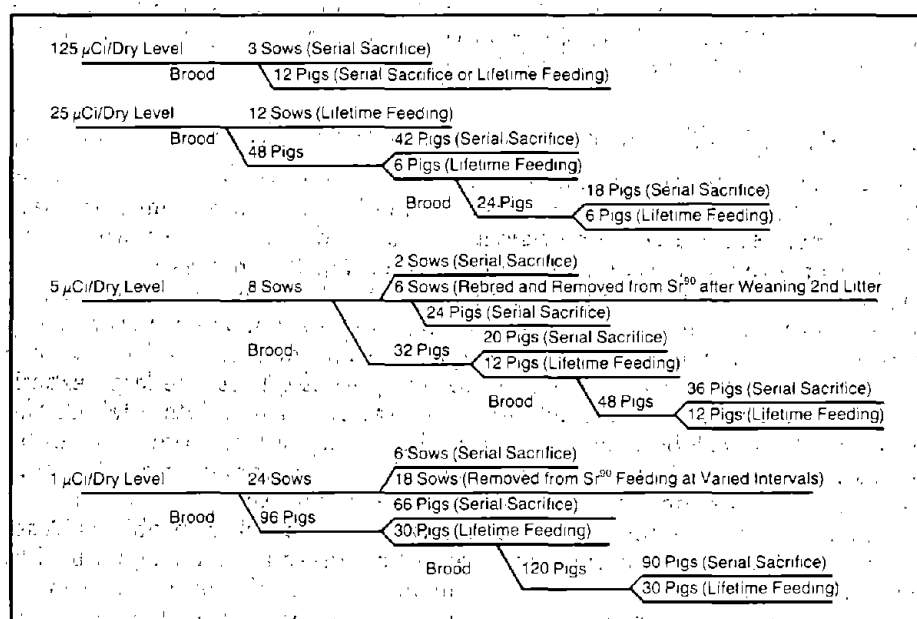

FIGURE 13.5. Plan of the Hanford experiment on ^{90}Sr in miniature swine. (Redrawn from McClellan et al. 1962. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1962.)

Besides general clinical effects, the development of hematopoietic effects, including myeloproliferative disorders, the development of bone and dental defects, farrowing performance, and fetal and neonatal changes were researched in depth. A picture of the laboratory facility developed for this experiment is shown as figure 13.6.

FIGURE 13.6. Laboratory facility at Hanford for housing miniature swine showing individual feeding compartments and ^{90}Sr pellets being fed. (From McClellan et al. 1962. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1962.)

2. Radiostrontium Studies in Pygmy Goats

This relatively small experiment was done for a species comparison with the swine on the one hand and laboratory rats on the other. Differences in both metabolism and effects were noted.

3. Passage of Pairs of Elements Through Food Chains

This work began with studies involving the passage of ^{90}Sr and stable strontium from soil to plants and the effect thereon of calcium content of the soil. This led to animal research, largely with rats, in which dietary intakes of this pair of elements were manipulated and the subsequent skeletal deposition measured. It led to a difference of opinion on the significance and utility of the "Observed Ratio" (OR) between Harry Kornberg, manager of the biology operation at Hanford and Cyril Comar at UT-AEC Farm (see section III). As in most such arguments, the truth lay between the extremes.^(a) The question is important to all research involving closely related elements. The Hanford work proved clearly that discrimination can be influenced markedly by conditions such as time and the concentration of the base-line element.

The work went on to look briefly at a second pair of elements, ^{137}Cs and stable potassium (details in the next section).

4. Radionuclides in the Fetal and Juvenile Mammal

Throughout the Hanford studies, much attention was directed to the placental transfer and metabolism of many of the radionuclides found in fallout in the fetus and the neonate (chapter 8). Not discussed there and to be reviewed herein was the reproductive performance of animals in the large experiment with radiostrontium in swine and changes in metabolism of some of the important elements in fallout with advancing age of the animal.

5. Research with Plants

The very first annual report of what was then the Biology Section of the Radiological Sciences Department of the Hanford Works describes research on the uptake of strontium, yttrium, cesium, and iodine from solutions by plants. It was shown that uptake was linearly proportional to concentration up to toxic levels and could be influenced by pH and by adsorption of the radionuclides on the roots of the plants. This work not only triggered some of the ideas and research concerning the behavior of pairs of isotopes, but extended to toxic effects of ^{137}Cs on cellular development of plants and later to the solubilization of plutonium and other transuranic elements in natural soils. Of particular interest was the different behavior of ^{238}Pu as compared to ^{239}Pu .

6. Aquatic Biology and Marine Sciences

The aquatic program at Hanford did not concentrate any special research efforts on fallout radionuclides. Much work was already under way on the effluents from reactors, fuel reprocessing, and other nuclear facilities, and most of the

(a) Obviously, no lasting problems persisted, since many years later Harry Kornberg and Cyril Comar became close colleagues at the Electric Power Research Institute in Palo Alto, California.

results have already been described (chapter 11). They are, of course, applicable also to fallout. There was much work on measurement and assessment of fallout radionuclides in marine biota (chapters 11 and 12), which included not only Richland and Hanford, but the Arctic, the Pacific, and the Columbia River and its environs.

There were, in addition to the areas named above, a few experiments to check on specific points, such as the relationship of the half-life of ^{137}Cs to body weight in humans (Eberhardt 1967) and some incidental work on uptake of transuranic elements in plants (Price 1972, 1973).

E. Los Alamos Scientific Laboratory, Now Los Alamos National Laboratory^(a)

The research at Los Alamos had a very general orientation. Despite the consistent and important participation of senior Los Alamos scientists in sounding the alarm concerning potential biomedical effects of fallout and making measurements in humans, animals, and the environment (see chapter 12), no single program there can be earmarked as stimulated by the problems of fallout. The single exception might be the work with plants spearheaded by Eric Fowler. Yet, much of the Los Alamos research has direct applicability to metabolism of fallout radionuclides. For example, the series of papers prepared over several years by Chester Richmond, J. Furchner, and colleagues and entitled, "Comparative Metabolism of Radionuclides in Mammals," has such applicability. This series, including graphs of the results, appears in chapter 8 along with a plan for electronic processing and analysis of the metabolic data (Richmond et al. 1964).

There was work, described in the annual reports from Los Alamos, on the effects of temperature and of hydration on retention in mice of radionuclides of importance in fallout (Furchner, Drake, and Richmond 1964; Furchner, Richmond, and Drake 1964, 1965; Furchner and Richmond 1963; Furchner et al. 1965), metabolism of radiocesium in man (Richmond, London, and Furchner 1964), distribution of ^{137}Cs in mice and dogs after chronic administration (Furchner, Richmond, and Trafton 1963), the effect of environmental temperature on retention of cesium in mice (Furchner et al. 1965), the long-term retention of cobalt in rats (Richmond and London 1967), and the disposition of ^{137}Cs during potassium depletion (Furchner and Drake 1973). All of these bear on understanding the behavior of fallout radionuclides. There were, in addition, the large efforts on the hot particle problem described in chapter 9, the work on tritium described in chapter 10, the many managerial and measurement activities around the tests described in chapter 12, and important contributions to the therapeutic removal of radionuclides to be described in chapter 19. Of special importance to the Los Alamos research of this period was the annular liquid scintillation counter described by Woodward, Richmond, and Langham (1956). There were studies on the retention of radionuclides in man using "Humco I," the fourth scintillation counter (e.g., Richmond, Furchner, and Langham 1962).

(a) I am greatly indebted to Dr. Robert G. Thomas for making available to me a complete set of the H-Division reports, for preparing extracts, and for providing selected reprints.

F. University of California at Los Angeles^(a)

The University of California at Los Angeles (UCLA) Project, except for its medical and nuclear medicine activities and some basic radiobiology, was largely devoted to work concerned with nuclear weapons testing and fallout therefrom. We have already met much of their work in chapter 12. There were also many laboratory projects, which concerned preponderantly the movement of fallout-type radionuclides in soils and plants and the influence of many factors in the environment. Some was semifield research, but much was done under greenhouse conditions.

In later years, the UCLA group became involved with general modeling for environmental transport, including cycling of nuclides in the environment of a Utah dairy farm and other food-chain transport, but this was more observational than research. The research and documentation will appear in sections III and IV.

G. University of Rochester

Research at the University of Rochester with radionuclides concentrated on alpha emitters such as polonium, plutonium, radon, and uranium, including chemical toxicity of uranium. As we saw in chapter 9, inhalation toxicology received much attention. In addition, the Rochester program considered long-term effects of external radiation, some of it pertinent to fallout problems. There was, of course, in addition, the ubiquitous graduate education program that covered all phases of radiation biology and toxicology.

There was a specific experimental foray into fission products and related radionuclides that concerned imbibed ^{90}Sr in monkeys and rats. This was done partly in response to the problems of fallout. The work with monkeys was similar to that at Berkeley, except for the route of administration. It was reviewed briefly in chapter 8. There was, in addition, detailed pathology done on the effects of ^{90}Sr in rats. Both experiments were sparked by Lawrence W. Tuttle, but the reports were produced largely by G. W. Casarett and colleagues. The findings will be included in the section on strontium in part IV of this chapter.

Della Rosa, Smith, and Stannard (1961) studied the renal clearance and behavior of strontium in the kidney and added a bit more detail to our knowledge of the mechanisms of discrimination for strontium over calcium at the point of excretion. This will be included in our general discussion of pairs of elements in section III.

Finally, the classic theoretical modeling done by H. A. Blair (chapter 8) had some pertinence to fallout radionuclides, especially plutonium, but was concerned as well with elements such as ^{226}Ra , ^{228}Ra , and ^{228}Th . The reader is referred to chapter 8 and the reference given therein for review of this facet of the Rochester contributions.

H. Lawrence Livermore Laboratory

We saw in chapter 12 that the Bio-Sciences Division of the Lawrence Livermore Laboratory (LLL) was developed primarily for research and assessment of the

(a) I am greatly indebted to Dr. E. M. Romney for making available to me a complete set of UCLA reports and the collected publications of the laboratory, for an illuminating interview and for selected copies and reprints.

problems of radioactive fallout. There was much work on aquatic systems and in the desert environment of NTS. The latter concerned primarily residual contamination with plutonium and will be considered in chapter 14. The aquatic biology work will be reviewed in section III.

I. Miscellaneous Other Operations

An interesting project pertinent to both aquatic biology and some of the radionuclides in fallout was carried out by Andrews and Warren (1969). Shields Warren, whom we have met at several points in this book, was interested in fisheries and aquatic biology, an interesting avocation for a pathologist. He operated on the premises of his summer cottage on Cape Cod, Massachusetts, an enterprise known as "Sea Farm Research Foundation." Andrews spent a summer there with fresh live clams and quahogs and measured their ability to concentrate ^{131}I , ^{85}Sr , and ^{59}Fe from sea water and to pass them on to the environment in feces. There were real differences between the two species as well as clear indications that the processes involved may be important for transfer of nuclides to bottom sediments. (More later.)

The work at the University of Washington Fisheries Laboratory, at the Woods Hole Oceanographic Institution, the School of Oceanography of Oregon State University, at the Puerto Rico Center, and at the Scripps Institution of Oceanography included many laboratory experiments directly related to fallout problems. Since we have already reviewed these programs in some detail in chapters 11 and 12, we will refrain from further description here, except to cite the experiments as appropriate in the following sections.^(a)

Work abroad was quite pertinent to the subject of this chapter. It will be reviewed briefly at the chapter's conclusion.

III. Selected Research Areas

We will consider now some of the results of research in the several laboratories described in sections I and II. Three major areas are chosen for review in this section: the metabolism of pairs of elements, i.e., a radioactive nuclide and its chemical congener, stable or radioactive; plants and soil-plant interrelationships; and findings in aquatic biology. In section IV, we will review the results collected together for the most important radionuclides in fallout. Work in the United States will be emphasized.

The period of greatest activity occurred in the late 1950s and 1960s, and we will concentrate on these years. Some of the work continued into later years, but it could no longer be called research stimulated by the problems of fallout.

A. Metabolism of Pairs of Elements— The Observed Ratio and Discrimination Factors

1. The Concept

When we considered the measurement of fallout in the environment in chapter 12, we were introduced to the idea of reporting the data for radionuclides

(a) A broad review of the entire problem of ecologic effects from radioactive emissions from nuclear power plants has been prepared by Rice and Baptist (1974). This includes reference to experimental work done at many installations named above.

such as strontium and cesium that had chemical properties very similar to elements already present in the environment, i.e., calcium and potassium in terms of the ratio of these two.^(a) We met the Strontium Unit (née "Sunshine Unit") which was defined as 1 pci (i.e., 1 μ ci) of ^{90}Sr per gram of calcium. Since the radioactive isotope was always present in gravimetrically very small quantities, it was logical to assume that its behavior would follow qualitatively and quantitatively that of its congener, calcium. The practice of using the ratio of the elements was followed quite faithfully in the early days of fallout reporting. Yet, there were many misgivings about its universal applicability and a strong stimulus was present to mount experimental research around this important concept and the biological mechanisms responsible. Particular emphasis was placed on dietary contamination and how to estimate concentrations in humans from those in the environment.

In the midfifties, Comar, Wasserman, and Nold (1956) presented a concept they expressed as the "Strontium-Calcium Observed Ratio." They also denoted the difference in behavior of strontium and calcium at various steps in the food chain as the "Strontium-Calcium Discrimination Factor." These were given acronyms of "OR" and "DF," respectively, and were generalized to any situation concerned with pairs of elements.

For strontium the OR was defined as:

$$\text{OR}_{\text{Sample-precursor}} = \frac{\text{Sr/Ca of sample}}{\text{Sr/Ca of precursor}}$$

Further, the OR was considered to be determined by the sum of the discrimination processes at the several steps, i.e.:

$$\text{OR} = (\text{DF}_1) (\text{DF}_2) (\text{DF}_3) \dots (\text{DF}_N)$$

The logic and some examples were given in this initial description. An eloquent and persuasive version of the logic was presented by Comar and Wasserman at the first major symposium on radioisotopes in the biosphere at the University of Minnesota (Comar and Wasserman 1960). Let us read the logic and application in their own words:

As early as 1958 there was an intuitive feeling that we should develop more data about the behavior of the "bone-seeking" fission products in the food chain, even though there was no recognition of the fallout problem as we now see it. Attention was soon focused on radiostrontium, and much work was done on the behavior of this radioisotope by itself in laboratory and domestic animals. As a matter of experience, often bitter, it is recognized that the behavior of any one substance in a biological system is often interrelated with other parameters that must eventually be taken into account. Accordingly, attention was turned to the comparative behavior and interrelations of strontium and calcium under normal nutritional situations as a beginning.

The early work of Pecher [and Pecher] (1941) had shown the similarities in behavior of strontium and calcium. Numerous studies thereafter showed that substances which modified calcium behavior also modified strontium behavior in a similar way (vitamin D, parathormone, lactose).

It appeared to some that the behavior of radiostrontium in the food chain was inevitably linked with the behavior of calcium. Furthermore, it seemed that to try to determine the behavior of radiostrontium in the animal or human population

(a) These were termed congeners.

without taking advantage of the long, hard lessons learned of calcium behavior was indeed wasteful of the experiences of others. As a specific example: We know that in the mature individual there is no net retention of ingested calcium—we would therefore expect no net retention of ingested radiostrontium under steady state conditions after the skeleton has been labeled; observations bear this out (Harrison et al. 1955). How then does one predict the radiostrontium level in the skeleton from knowledge of the intake? And how does one determine the radiostrontium concentration in the newly-forming areas of bone from knowledge of the intake? There seemed little question that the information needed—namely the relationship between radiostrontium in the diet and in the human population—is to be obtained with much more certainty by consideration of strontium-calcium behavior than by consideration of strontium behavior alone.

(Comar and Wasserman 1960, p. 526)

Practical use of observed ratios:

The practical use of an Observed Ratio for prediction purposes depends primarily upon whether a given value or range of values is generally valid. A comment may then be in order as to the variability that might be expected in the differential behavior of strontium and calcium in the mammal.

Examination of data obtained by independent methods in many laboratories and many countries has indicated that under usual dietary conditions the OR values fall within a reasonably narrow range, with few indications of variations as high as a factor of two. There appears to the authors a remarkable constancy, especially for dealing with populations and with considerations that contain uncertainties of much higher order.

It is recognized, and, as a matter of fact, early pointed out by the authors, that the OR values can be changed by unusual dietary modifications. Also, it was shown that in very early life, rats have less discrimination against strontium; the differences were small in later life (Comar et al. 1957). These limitations must always be borne in mind and OR values used only when they can provide some advantage.

(Comar and Wasserman 1960, p. 531)

And still later:

For radiostrontium, it appears that consideration of strontium-calcium ratios is of much greater usefulness than consideration of strontium retention alone. The reasons can be summarized: (a) There appears to be a reasonably constant relationship under normal dietary conditions between strontium-calcium ratios in diet and those in the body or milk; (b) The strontium-calcium ratio predicted in the body at any given time will reflect the radiocontamination at the local areas in bone that are active at the time; (c) Radiostrontium retentions will vary greatly with age, diet, and other factors; in mature individuals retention will progressively decrease to zero as the skeleton becomes labeled under constant intake; calcium retentions would be expected to be parallel; (d) The behavior of radiostrontium ingested will be related to the calcium intake; (e) The calcium level of the body is reasonably constant regardless of dietary intake under adequate or optimal conditions; the calcium of blood is under close homeostatic control and tissues are similar in calcium content. This behavior of calcium makes it a good standard of reference; (f) Calcium metabolism and nutrition have been widely studied in the past.

For radiocesium there apparently is not the close relationship with potassium as has been observed for strontium-calcium. Much more data are required for an understanding of cesium behavior and the effects of the important parameters.

(Comar and Wasserman 1960, p. 539)(a)

(a) References given in the above quotations have been added to the bibliography for this chapter.

Much research was done to determine: (1) whether or not the OR was indeed reasonably constant and thus useful to the degree implied above, (2) the differential behavior of calcium and strontium in physiological processes, and (3) their possible mechanisms. We will consider these in turn.

2. Is the Observed Ratio for Strontium/Calcium Reasonably Constant?

Some examples of strontium-calcium observed ratios in animals for the process diet-to-bone are shown in table 13.2A and B, which is taken from Comar and Wasserman (1960), who in turn obtained it from one of the early United Nations (UNSCEAR) reports. Similar figures, but concerning diet to milk, are shown in table 13.3.

TABLE 13.2A. Strontium-Calcium Observed Ratios in Animals; Diet to Bone

Species	Diet	Method	Remarks	OR Value
Cow	normal	dbbl. tracer	8 animals	0.21

Cow	Sr ⁹⁰ /Ca in U.K. surveys	0.09
Cow	Stable Sr/Ca ratios in U.S.	0.12
Goat	Dbbl. tracer daily	0.09

Source: Modified slightly from Comar and Wasserman 1960 who obtained the data from the 1958 UNSCEAR report. Reprinted with permission of the University of Minnesota-Twin Cities, Minneapolis, Minnesota, copyright 1960.

These values do indeed look reasonably constant considering the chances for variability in such systems. Note, however, that the OR for diet to bone in man appears to be higher in general, although probably not statistically significantly higher, than in animals. Note also that the OR for diet to milk is lower in lactating animals than from diet to bone, which reflects a fairly general finding, viz., the OR values for different physiological processes are not the same. For example, in the rat, when considering placental discrimination, the OR from diet to mother was 0.28, from fetus to diet 0.17, from mother to urine 4.7, and from fetus to mother 0.71.

In the lactating goat, the OR from diet to milk was 0.09, from diet to plasma 0.23, from plasma to milk 0.40, from plasma to urine 16, and from diet to urine 4 (Comar and Wasserman 1960, p. 530). These differences reside in the different discrimination processes involved.

An important test of the practical constancy of the OR for strontium/calcium would be the effect of variations in the calcium or strontium intake using either stable or radioactive isotopes. Comar and Wasserman (1960) report OR values for a number of processes in the lactating cow and the lactating goat on diets with varying calcium or stable strontium content. The calcium intake was varied from about one-half the normal to three times the normal level starting three weeks before the experiment. As shown in table 13.4A and B, the OR values were satisfactorily alike, particularly the OR_{milk-diet}.

Further investigation, particularly at Hanford, indicated that the relationships were sometimes far from a strict proportionality. Verbatim application of the philosophy behind the use of OR for hazard evaluation, for example, predicts that bone deposition of radiocalcium or radiostrontium should be inversely proportional to the dietary calcium level. At the Minneapolis symposium we have been quoting, Roy Thompson from Hanford presented data gathered by Ray Palmer and his associates, also at Hanford, on the buildup of ⁴⁵Ca and ⁹⁰Sr in rat bone during periods of chronic feeding of diets with calcium contents ranging from 0.03% to 2.0% (Thompson 1960). There was the expected effect qualitatively, less bone deposition of both ⁴⁵Ca and ⁹⁰Sr as the dietary calcium increased. However, the relationship was not an inverse proportionality. Whereas the dietary calcium covered a sixty-seven-fold range, the change in radiocalcium deposition was only sixteenfold and that of radiostrontium only fourfold. This is not surprising, if one considers that the bone deposition can only be related to blood calcium and not directly to that in the diet. The deposition of ⁴⁵Ca in bone turned out to be essentially proportional to the levels of ⁴⁵Ca in

TABLE 13.4A. OR Values in the Lactating Cow

blood. As Thompson remarks, "The bone simply isn't aware of the dietary calcium level. It sees only the calcium in the blood . . ." (Thompson 1960, p. 519).

The variations in the $OR_{\text{bone-diet}}$ as a function of both the calcium intake level and of time in the experiment are shown in figure 13.7. Obviously, a range from an OR of about 0.47 on a high calcium diet at one day to about 0.08 on a low calcium diet at one hundred days, the extremes seen in the figure, could have a large effect on the usefulness of the OR if applied uncritically for hazard evaluation.

FIGURE 13.7. Observed Ratio (bone-diet) during period of chronic feeding of diets of various total calcium content to rats. (Modified slightly from Thompson 1960. Experiment of Palmer and colleagues at Hanford. Reprinted with permission of the University of Minnesota-Twin Cities, Minneapolis, Minnesota, copyright 1960.)

A view of a chronic feeding experiment at Hanford carried from weaning to two hundred days in rats is seen in figure 13.8A and B. Although the spread in figures is rather large, and the ranges overlap, the difference between 0.1% calcium and 0.5% calcium in the diet appears large. Why the 2% calcium diet should produce OR values between these two is not clear.

FIGURE 13.8A. Observed Ratio (bone-diet) in rats fed from weaning on ^{90}Sr - and ^{45}Ca -labeled diets of various total calcium contents. (Redrawn from Thompson 1960, using data of Palmer, Thompson, and Kornberg 1958. Reprinted with permission of the University of Minnesota-Twin Cities, Minneapolis, Minnesota, copyright 1960.)

FIGURE 13.8B. The same data as in figure 13.8A plotted with shading for the ranges. (Redrawn from Kornberg 1960. Reprinted with permission of the University of Minnesota-Twin Cities, Minneapolis, Minnesota, copyright 1960.)

Further consideration of the lack of inverse proportionality between dietary calcium and deposition of ^{45}Ca or ^{90}Sr is pictured in figure 13.9, taken from a discourse by Harry Kornberg from Hanford.^(a) Note here that the ordinate is not OR. Yet, the lack of linearity is clear as well as the moderately large standard deviations. As stated, straight lines should have resulted if strontium and calcium have a linear inverse relationship.

FIGURE 13.9. Effect of dietary calcium on skeletal deposition of Sr^{90} in rats. Straight lines should have resulted if strontium and calcium have a linear inverse relationship to each other (width of lines is proportional to standard deviations). (Kornberg 1960, using data from Palmer 1958. Reprinted with permission of the University of Minnesota-Twin Cities, Minneapolis, Minnesota, copyright 1960.)

As we will see in a following section, the discrimination mechanisms underlying the OR are not fully developed in the very young. Thus, age can influence the OR. In an erudite review concentrating on mechanisms, Comar (1967) presents a summary of $\text{OR}_{\text{body-diet}}$ in young children as related to age and gives a single point for the $\text{OR}_{\text{body-mother's diet}}$ in a newborn. These vary from nearly 1 in the very young to the usual value seen in adults of between 0.2 and 0.3 beginning at about sixteen months of age. These are full balance studies and are shown in figure 13.10.

(a) See also figure 13.8B.

FIGURE 13.10. $OR_{body/diet}$ as related to age of young children. \circ , Beninson, Migliori, and Ramos (1964), ^{90}Sr ; \square , Beninson, Migliori, and Ramos (1964), Sr ; \bullet , Lough, Rivera, and Comar (1963), ^{90}Sr ; Δ , Comar (1967), New-born, $OR_{body/mother's\ diet}$. The references given in this legend have been placed in the bibliography. (Redrawn from Comar 1967 and reprinted with permission of Academic Press, New York, copyright 1967.)

An illustration of the behavior of the observed ratio of strontium to calcium in growing beagles is shown in figure 13.11, which comes from the large experiment at the University of California at Davis (see section I).

FIGURE 13.11. Observed Ratio as a function of age in beagles. The dotted area on the left represents suckling: broken lines, pup body/milk; continuous line, pup body/maternal diet. Discrimination is low for the first 30 days or so but reaches a more or less constant and higher figure by 100 days. The lower solid line represents the OR from the pup body versus the maternal diet and has interposed the factors

for gut uptake etc., by the mother as well as the factors in the pup represented by the broken line. (Redrawn from Goldman and Della Rosa 1967. Reprinted with permission of Academic Press, New York, copyright 1967.)

It is clear from the experimental work quoted that the OR for strontium versus calcium is hardly a rigid constant, that it can be varied by such factors as age and the dietary intake of calcium or stable strontium. Yet, the ratio is sufficiently

constant under the conditions of most interest to be useful. Any problems with its application may arise from failure to take cognizance of the necessary caveats. Comar, Russell, and Wasserman (1957) emphasize the care needed to ensure that the ratios measured truly represent the quantities available to the organism.

It is at the first step, soil to plant, that the largest source of error may occur in calculation of the overall OR. This was the source of Kornberg's concerns for the usefulness of the OR concept as indicated earlier (section II). The preamble to Kornberg's dissertation on the subject is given below.

As often happens in research, we began a series of investigations after making some observations that seemed to be at odds with common sense. For example, it seems common sense to say that if a plant takes up 10 Sr^{90} atoms per second from the soil, then if we add to the soil 9 inert strontium atoms for each Sr^{90} atom there, the plant should now take up only 1 Sr^{90} atom per second. But when essentially such an experiment was done by Rediske, Cline, and Selders (1955), the results did not bear this out. Instead, the same number of Sr^{90} atoms went up the plant, regardless of the number of inert strontium atoms that were present in the root environment.

Such a result may seem odd until one thinks in terms of basic mechanisms. It is not that the plant insists on taking up 10 Sr^{90} atoms per second, regardless of inert strontium atoms present. Instead, the rate governing process in this case seems to be the flow of solution up the plant. Under such conditions it does not matter what solutes are present along with the Sr^{90} .

Cline and Hungate (1956) obtained similar results when calcium atoms were used to dilute Sr^{90} atoms in soil. Again the uptake of Sr^{90} was not depressed by increasing soil calcium. It was about at this time that public interest in the hazards of fallout became widespread, and it was popularly asserted that the hazard of Sr^{90} was inversely proportional to the concentration of calcium in the environment. This, of course, was quite contrary to our results, at least in plants. The difference between what we read in the papers and what we saw in the laboratory started us attempting to find which was right.

Before long Hungate, Uhler, and Cline (1958) found that calcium could, indeed, depress the uptake of Sr^{90} into plants. However, this occurred only in acidic soils low in calcium. But even here we did not observe a linear inverse relationship in depression of Sr^{90} uptake with increase of calcium. Fredrikson et al. (1958) observed similar effects and pointed out that the uptake of Sr^{90} into plants is not inversely proportional to soil calcium.

(Kornberg 1960, pp. 255-256)^(a)

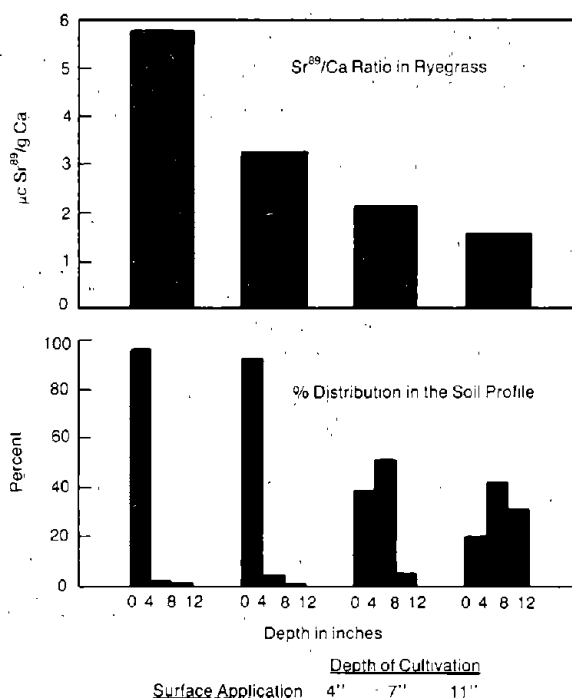

This plant work was the impetus for the work with rats at Hanford already discussed.

Kornberg also shows work done by Uhler (1959) where bean plants were grown in nutrient cultures containing ^{85}Sr , ^{45}Ca , and different concentrations of stable calcium to see what effect calcium concentration would have on the strontium/calcium ratio within the plants. There was a marked effect in roots, less marked in stems, and essentially no effect in leaves. Thus, it appeared that the plant did not discriminate either for or against strontium in the transfer of the strontium-calcium pair to the leaves that are the components most likely to become forage for cattle.

(a) References in the above quotation have been added to the bibliography for this chapter.

There are many problems under practical conditions. Radiostrontium is unlikely to be homogeneously mixed throughout the soil. In fact, great care must be taken to ensure proper mixing for any laboratory experiment. There is no way to express the strontium/calcium of the nutrients to which the roots themselves are exposed under most field growth conditions. If the soil is not cultivated, the strontium will tend to reside primarily in the upper layers and move downward slowly with time. Cultivation can, of course, hasten the mixing. Russell (1960) discusses work by Milbourn, Russell, and Ellis (1959) showing the ratio of $^{89}\text{Sr}/\text{g Ca}$ in ryegrass and also the extent of mixing of the ^{89}Sr in the soil profile as a function of depth of cultivation. The results are shown in figure 13.12.

FIGURE 13.12. Distribution of Sr^{90} in the soil profile and ratio of Sr^{90} to calcium in ryegrass grown on land which was either contaminated on the surface or to varying depths by cultivation before the sowing of crops. (Redrawn from Russell 1960 taken from data of Milbourn, Russell, and Ellis 1959. Reprinted with permission of the University of Minnesota-Twin Cities, Minneapolis, Minnesota, copyright 1959, 1960.)

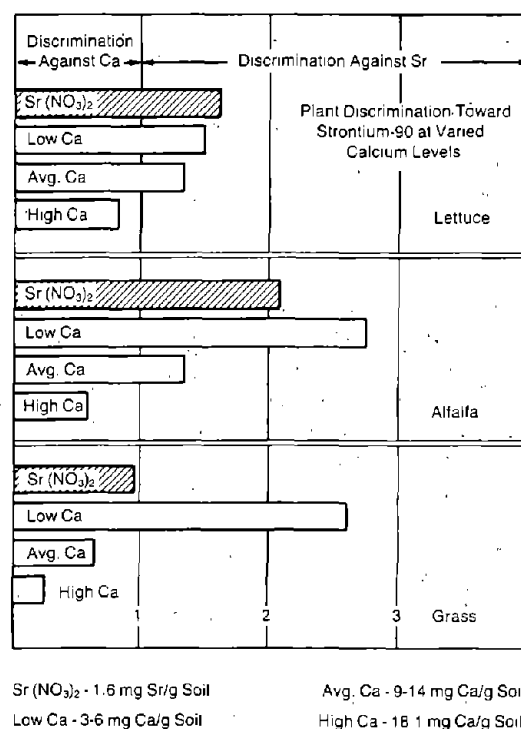

It is clear, as one might surmise intuitively, that an OR involving soil-to-plant interactions could be sadly misleading if either the soil were not mixed or the concentrations seen by the roots were not the ones measured. This is a significant difference between laboratory and field conditions. In the laboratory, with strontium well mixed with the soil, the observed ratio seems to vary within narrow limits over a wide range of concentrations of calcium in soil (see Fredrikson et al. [1958] as well as research mentioned earlier), and in general seems to be nearer to unity than the OR values for such processes as bone to diet, etc.

Another factor, mentioned by Eisenbud (1973, p. 130), is that a portion of the radiostrontium in the soil may become unavailable to plants as a result of chemical reactions in the soil.

Even though the discrimination factor between plant and soil tends toward unity more than that of other processes, it should not be concluded that this always applies, even under the best of laboratory conditions. An example of the variations possible under varying conditions of calcium content of the soil and for different plants in a good laboratory experiment is shown in figure 13.13, taken from Adams, Christenson, and Fowler (1965) from Los Alamos.

FIGURE 13.13. Plant discrimination toward ^{90}Sr at varied calcium levels. (Redrawn from Adams, Christenson, and Fowler 1965. Reprinted with permission of Elsevier Science Publishers, Amsterdam, copyright 1965.)

It should be noted that discrimination is toward strontium at low calcium and against strontium at high calcium, even though there is indeed little discrimination either way at average calcium with the exception of grass.

Results of a similar nature can be found in extensive work at UCLA using barley, buckwheat, cow peas, some grains, and some vegetables (Nishita, Romney, and Larson 1965). We will review the actual experiments briefly in a following section.

What can we conclude from the above? Clearly the OR concept has utility when used correctly. Wasserman (1960) concludes:

Although the observed ratio (OR) may be confusing to the uninitiated, it certainly is the only rational method for calculating the differential movement of two similar ions from one physiological compartment to another. If an atom ratio for Sr/Ca in a product compartment is observed to be 1/10, this ratio will only have meaning in terms of comparing the movement of calcium and strontium across boundaries if the atom ratio of Sr/Ca in the precursor compartment is known. The observed ratio merely formalizes this relationship where, by definition, the OR is the Sr/Ca ratio in the product compartment (e.g., skeleton) relative to the atom ratio of Sr/Ca in the precursor compartment (e.g., diet). Using the observed ratio as defined, the comparative movement of calcium and strontium in gastrointestinal absorption, urinary excretion, kidney clearance, placental transfer, and mammary transfer can be readily calculated from suitable observations. (Wasserman 1960, pp. 568-569)

In contrast, Kornberg was impressed by the lack of inverse proportionality and the variability of the OR and felt that these limited its usefulness for hazard assessment. He wondered if more conventional units might not do as well. He was impressed, however, by the contributions the concept of the ratios can make to fundamental biology.

Thompson took the view that the ratio approach simplifies the problems of hazard evaluation but that those primarily concerned with biological

mechanisms may be more impressed by the differences in the behavior of the ions than the similarities!

3. Other Pairs of Elements

Much research was done in several of the laboratories discussed in sections I and II on the behavior of cesium versus potassium. We saw in chapter 12 that the fallout-generated ^{137}Cs in inhabitants of Jamaica was higher than in persons from many other areas, apparently because the soil of the region was low in potassium.

Cesium is quite firmly bound in soils, which has the effect of indicating heavy "discrimination" by plants against cesium. It is not physiological discrimination. Langham and Anderson (1959) cite work of Auerbach (1957) at Oak Ridge showing that corn grown in the White Oak Lake bed (chapter 11) had a $^{137}\text{Cs}/\text{K}$ ratio of only 0.01 of the exchangeable $^{137}\text{Cs}/\text{K}$ in the soil. Also, Menzel (1954) reported a "discrimination factor" of 0.04 in the $^{137}\text{Cs}/\text{K}$ ratio of barley and corn versus the ratio in the soil. This type of "discrimination" is, of course, mechanistically quite different from the strontium/calcium discrimination we have been considering, since it involves the chemical state of the material to be absorbed, not the processes of absorption.

There was some effect of potassium concentration. Menzel (1954) showed that plant uptake of ^{137}Cs was inversely proportional to exchangeable soil potassium. However, with 75% or more of the cesium in the soil unavailable to plants, any changes in cesium behavior caused by potassium concentration are bound to have a relatively small effect overall. Also, an observed ratio for cesium/potassium could be meaningless unless it referred only to the mobile forms of cesium and potassium.

The situation in animal processes is somewhat more regular but not qualitatively different. The ^{137}Cs is readily transferred from diet to milk in the lactating mammal with a cesium/potassium ratio of about 1.4 in both cow and goat. This is interpreted as indicating little, or at least only slight, selection. There was something resembling an inverse ratio of cesium and potassium in animal tissues, but these seemed to apply mostly to situations with deficient diets.^(a) The observed ratio $^{137}\text{Cs}/\text{K}$ for muscle versus diet was not a constant (Wasserman et al. 1965). The value of

$$\frac{^{137}\text{Cs}/\text{K muscle}}{^{137}\text{Cs}/\text{K diet}}$$

ranged from 1.0 to 5.3 when the level of dietary potassium ranged from 0.2% to 1.8%. Comar and Wasserman (1960) found that the $^{137}\text{Cs}/^{42}\text{K}$ ratio also varied considerably among tissues in the same animal, i.e., 0.3 to 3.7 and, in the lactating goat, at least, it did not correlate with the total potassium content of the tissues. A ninefold difference in dietary potassium caused only a twofold difference in the ^{137}Cs concentration of muscle (Wasserman 1960). It appears that cesium and potassium behave relatively independently of each other, and their movements in the body are competitive to only a small degree.

(a) The people at the UT-AEC Farm (Mraz and Patrick 1957) found that increased dietary potassium decreased the retention of ^{137}Cs only when the animal was in potassium deficiency. If adequate levels of dietary potassium were already present, further increase had no effect on the retention of radiocesium.

Despite these facts, some practical use can and has been made of the cesium/potassium ratio, particularly for environmental contamination.^(a) On the basis of an extensive survey of cesium in milk and other foods, the Los Alamos group (Langham and Anderson 1959) decided that an average discrimination factor of about two against potassium existed in the passage of cesium from diet to the tissues of humans. As indicated in figure 13.14, an overall OR for both plant and animal sources can be determined as $0.5 (0.01 \times 2 \times 2) + 0.5 (0.01 \times 2) = 0.03$, assuming that about half of the dietary potassium comes from plants and half from animal sources and that the step from soil to plant has an OR of 0.01.

FIGURE 13.14. Ecological discrimination against Cs^{137} with respect to potassium (U.S. population). The subnumerals in the figure are: b = body, p = plant, m = milk and s = soil. (Redrawn from Langham and Anderson 1959. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1959. See also Langham 1965.)

There were theoretical reasons to expect rubidium and potassium to behave as a pair; in fact, rubidium is sometimes substituted for potassium in tracer studies. Some examples of rubidium-potassium discrimination in plants are referenced in Nishita, Romney, and Larson (1965). We will not follow these further since rubidium is not important among the fission products. Ruthenium (e.g., ^{106}Ru) is important and does distribute differently in different tissues, but this is not because it is paired with anything else.

Special cases of paired behavior for different isotopes of the same element have been the subject of many investigations. The best examples are seen with isotopes of iodine and plutonium.

(a) This will be considered in more detail in part 6 of this section.

It has become well established that longer-lived iodine isotopes (e.g., ^{131}I) seem to be less effective per rad of absorbed dose compared to shorter-lived isotopes such as ^{132}I , ^{133}I , and ^{135}I and low-LET external x- or gamma-radiation. The factor has been placed as high as twenty but in recent years has been reduced to ten and very recently has been conservatively placed at three for long-term effects in man (NCRP 1985). This difference may reside in relative specific activities.

The difference in both behavior and effectiveness of ^{238}Pu versus ^{239}Pu clearly resides in difference in specific activities with, for example, much more radiolysis of the medium and the various colloidal complexes of plutonium in the case of the shorter-lived ^{238}Pu . Neither of these involves discrimination of the type discussed above, but the end result can be comparable.

4. Discrimination Factors

If there is no selective metabolism or transfer of one element of a pair over another, the OR as defined in the previous section would be unity. The fact that it is frequently not unity means that there is differential handling either for or against one element over the other. Comar, Wasserman, and Nold (1956) called these processes "discrimination," as we have already seen, and the measure of it a "discrimination factor" (DF).^(a) For a pair like strontium-calcium, the DF is conceptually the inverse of the OR. This was followed up in humans by Comar, Russell, and Wasserman (1957).

Much effort was expended in determining discrimination between strontium and calcium at each major step in the food chain. As indicated above, the factor between soil and plant for strontium-calcium was small enough and uncertain enough (partly because of incomplete mixing of the radiostrontium with soil) to be considered as unity. However, for absorption from the gut, excretion in the urine, secretion into milk, and placental transfer, there was clear evidence for discrimination. It was always for calcium and against strontium if one defines "for" and "against" as in the direction most favorable for having the minimal body or bone burden of radiostrontium. In simple terms, the absorptive and urinary discrimination can be represented by:

$$\begin{aligned} \text{DF}_{\text{absorptive}} &= \frac{100 - \% \text{ radiostrontium in feces}}{100 - \% \text{ radiocalcium in feces}} \\ \text{DF}_{\text{urinary}} &= \frac{\text{OR}_{\text{retained - diet}}}{\text{DF}_{\text{absorptive}}} \end{aligned}$$

Some early quantitative values for these are shown in table 13.5, taken from the landmark paper by Comar, Wasserman, and Nold (1956). Immediately apparent from this table is the fact that discrimination against strontium is greater for absorption from the gut than for urinary excretion and that diet can influence the absorptive discrimination markedly.

In pregnant rats, it was clear (Wasserman et al. 1957) that placental discrimination occurred against strontium such that the $\text{DF}_{\text{placenta-fetus}} = 0.65$. Absorptive and urinary discrimination factors in the pregnant rat were 0.42 and 0.63, respectively. The phenomenon was confirmed qualitatively in other species.

(a) The idea was already in use in many areas of mineral metabolism and elsewhere but Comar et al. introduced it specifically for the strontium-calcium pair and did not quote any previous use of the term.

TABLE 13.5. Strontium-Calcium Discrimination Factors in the Rat

Diet	Milk	Milk and corn	Commercial
OR urine-diet			
OR blood-diet	4.3	3.4	5.2
DF urinary	.84	.84	.88
DF absorptive	.68	.66	.34
OR retained=	.57	.56	.30
(DF urinary) (DF absorptive)			

Source: Reset from Comar, Wasserman, and Nold 1956. Reprinted with permission of the Society for Experimental Biology and Medicine, New York, copyright 1956.

The discrimination in lactating animals has been worked out in many species, including the human. In the lactating goat (Wasserman, Lengemann, and Comar 1958), the DF absorptive averaged 0.24, the DF_{urinary} averaged 0.60 and the DF_{lactational-milk} averaged 0.61. Thus, the OR_{milk-diet} was about 0.09 (i.e., $0.24 \times 0.60 \times 0.61$), or an overall discrimination factor of about 11.1.

Discrimination factors for the lactating cow and human were found to be similar, i.e., average OR_{milk-diet} about 0.11 or an overall discrimination factor of about 9 in the cow and 0.10 and 10, respectively, in round numbers in the human. The results of these processes and the influence of diet in the lactating cow can be seen in the figures illustrated in table 13.6. Note that the percentage of the daily dose of ⁴⁵Ca appearing in milk is about ten times the percentage of ⁸⁹Sr, whether expressed in terms of daily dose per liter or per day, while the amount of calcium in feces and in urine is less than strontium, although only

slightly less. The excretion of strontium in urine is not greatly different from calcium, except on a low-calcium diet.^(a)

Note that the experiment was on animals in a steady state, i.e., no changes in dietary intake or in the metabolism of the organism were occurring (e.g., the animal was not growing, the diet was constant, etc.). We will return to this point in part 6 of this section.

Physiological processes showing little or no discrimination between strontium and calcium are: blood to skeleton^(b) (Comar and Wasserman 1960; Bauer, Carlsson, and Lindquist 1955); also excretion of the two elements from blood into the intestinal tract via the intestinal mucosa, the bile, and pancreatic juices (Greenberg and Troescher 1942) appears to be comparable.^(c) We have already seen that discrimination in the soil-root system for strontium-calcium is frequently considered to be negligible. A table of actual figures taken from experimental work at UCLA is shown as table 13.7.

TABLE 13.7. Strontium-Calcium Discrimination Factors for Plants Grown in Various Soils Under Different Conditions

Plant	Basis for* calculation	Number of soils studied	Extracting solution	Culture method	D.F. value
Barley	II	1	NH ₄ Ac(pH 7)	can (3.5 kg)	0.39-0.45
Buckwheat					0.43-0.49

- (a) Note that these are not OR values and that the ratio in the diet is not given in the table. Thus, any DF values derived will not be in the same terms as those we have been using.
- (b) Comar, Wasserman, and Nold (1956) suggest that strontium in the blood may actually be preferentially deposited in bone, but the small amounts of radiostrontium in the blood made accurate measurements difficult.
- (c) There is some evidence that about twice as much radiostrontium as calcium is secreted into bile (unpublished observations in Comar's laboratory), but the total excretion of radiostrontium into the gastrointestinal tract is only about 20% greater than that of calcium.

These were all laboratory-type experiments or field experiments under controlled conditions. Obviously, there are many conditions under which the strontium-calcium discrimination in soil to plant is well below unity. These refer to the whole plant; DF values for different parts of plants can vary considerably. Thus, Auerbach and Crossley (1958) found in the corn experiment in White Oak Lake bed at Oak Ridge that the DF (strontium-calcium) could be 0.5 for the grain and 2.8 for the flower. There are many other examples of differences between parts of plants (see, for example, Nishita, Romney, and Larson 1965). These show that there can be discrimination within plants as well as between soil and plant. Similar differences between parts of plants have been found with the cesium-potassium and the rubidium-potassium pair.

In hazard evaluation, it is conservative to assume no discrimination at the soil-plant step. This, plus the considerable spread in experimentally obtained values, underlies the common practice. The research shows that this is not always true or that simple (see specific researches on plants).

Formulations for lactational discrimination and for placental discrimination are somewhat more complicated but utilize the same principles. These are shown as note 4 at the end of this chapter.

5. Mechanisms for Discrimination

The possible mechanisms underlying the phenomena of discrimination between strontium and calcium have been subjected to very active experimental investigation. The mechanisms uncovered undoubtedly apply to many other discrimination processes.

An early approach was on the basis of homeostatic control. In higher vertebrates, calcium content of blood and tissues is under fairly rigid control (i.e., homeostasis). As we will see in chapter 19, one of the severe limitations on the therapeutic removal of radionuclides deposited in bone is possible interference with calcium homeostasis, particularly the removal of excessive amounts of calcium. Strontium metabolism is not regulated around some normal concentration of stable strontium, i.e., there is no homeostasis for it. It is not surprising, therefore, that it behaves differently from calcium, but why should the difference always be in one direction?

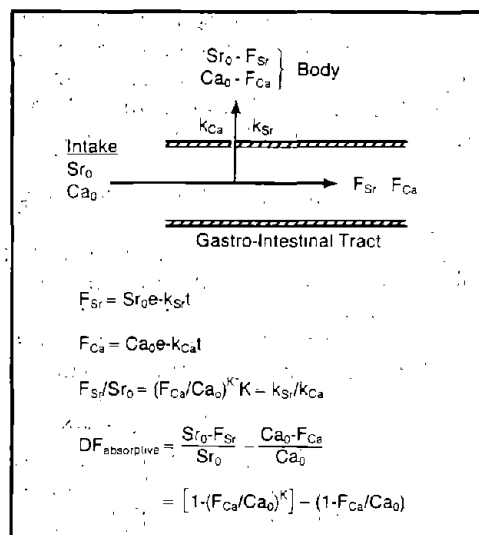

A second approach depends upon the relative rate constants for transfer across biological membranes. If calcium, for example, is absorbed from the gastrointestinal tract faster than strontium, there will in time be an enrichment of strontium in the remainder solution. The processes can be considered to have first order kinetics and can be modeled as in figure 13.15. The final solution from figure 13.15 can be written as:

$$DF_{\text{absorptive}} = \frac{1 - (F_{\text{Ca}}/Ca_0)K}{1 - F_{\text{Ca}}/Ca_0}$$

where K represents the comparative fractional rate constants for strontium and calcium (Comar 1967), F_{Ca} is calcium in feces, and Ca_0 is the stable calcium.

Marcus and Wasserman (1965) found that this equation held for gastrointestinal absorption in rats; and similarly Walser and Robinson (1963) found that it could apply to tubular reabsorption in the kidney of dogs and humans. The value of K was about 0.7 in these cases.

FIGURE 13.15. Expression of discrimination in terms of rate constants. The expressions F_{Sr} and F_{Ca} refer to amounts in feces, and are thus a rough measure of the amount not absorbed. K is the ratio of the rate constants K_{Sr} and K_{Ca} . (Redrawn from Comar, 1967; Reprinted with permission of Academic Press, New York, copyright 1967.)

The kinetic analysis needed to be fleshed out with more penetrating mechanistic investigations. This was carried out in several of the laboratories reviewed in sections I and II. Two of the approaches used will be considered here; first, the knowledge gained by research in which conditions were changed, and second, direct studies of physiological processes.

The first approach includes, but is not limited to, the effect of diet and age. It was found that the data shown in figure 13.10 could be explained by changes in the $DF_{absorptive}$ (DF_A). Harrison, Raymond, and Tretheway (1955) in the United Kingdom measured DF_A in infants as 1.06, i.e., essentially no discrimination. By contrast, work of Spencer et al. with adult humans found an average DF_A of 0.42. The $DF_{urinary}$ was about the same in both, viz., 0.79 in infants and 0.70 in adults. This work showed that the gastrointestinal tract of the infant lacks the mechanism operating in the adult. This may well relate to other known defects in the gastrointestinal tract absorptive mechanisms of infants.

The effects of dietary changes have pointed indirectly to mechanisms. For example, lactose fed to rats raises the DF_A value. It turned out that it did so by increasing calcium absorption (Marcus and Wasserman 1965).

As early as 1959, Schachter and Rosen (1959) demonstrated in isolated intestine that radiocalcium is actively transported, while strontium ions are not. Also, Wasserman, Kalfetz, and Comar (1961) used an everted rat duodenal sac preparation and showed that calcium could move against a concentration gradient in the absorption process, prima-facie evidence of an active transport process. Furthermore, the process seemed to depend on keeping intact the processes of oxidative phosphorylation (Taylor 1967). This was based on the effect of specific inhibitors of oxidative phosphorylation.

Comar and Wasserman (1960) mention seeing two phases of adaptation to decreases in dietary calcium as measured by calcium and strontium absorption. They speculate that one of these may represent the active transfer process, which appears to be easily saturated and cannot account for the whole of calcium transport under many circumstances.

Palmer and Thompson from Hanford (1961) used a somewhat improved technique by perfusing a segment of the rat intestine *in vivo*. This followed earlier methodology used by workers at Harvard (Dumont, Curran, and Solomon 1960) that had already shown that absorption of strontium followed kinetics of a passive diffusion process, while that of calcium showed evidence of an active transport process at higher concentrations of calcium in the intestine. While Palmer and Thompson claim that their work was not designed to elucidate mechanisms of absorption but only to measure discrimination during absorption, and it is true the data do just that, they show that discrimination does occur in the intestine. We view that as mechanism oriented.

Palmer and Thompson used ^{85}Sr and ^{45}Ca , the familiar double tracer of the time, and found that the percentage of ^{85}Sr absorbed was 0.3 that of calcium when no calcium was added to the perfusion fluid. As calcium concentration in the perfusion solution was increased, the amount of both ions absorbed decreased, but the ratio of ^{85}Sr to ^{45}Ca increased to about 0.6.

Still further into detail, Comar (1967) referred to work under way in the Cornell laboratories that indicates the following: strontium and calcium enter the intestinal mucosal cells at about the same rate, but calcium is moved out at a faster rate. This faster rate of transport may rest on the presence of a binding factor for calcium. This factor is considered to be a protein or associated with a protein.^(a)

What of the discrimination process in the kidney? The Walser and Robinson work was first developed to illuminate renal discrimination. They concluded that the value of K , the ratio of the rate constants k_{Sr} and k_{Ca} , is about 0.7. Comar followed this up (1967) in work evaluating the relation between $\text{OR}_{\text{urine-diet}}$ and urinary calcium concentration. Seemingly intuitively he concluded that the physical meaning of the ratio of rate constants $k_{\text{Sr}}/k_{\text{Ca}}$ represented the ratio of rate constants for tubular reabsorption of strontium as compared to calcium. Thus, the value of 0.7 (actually 0.5 to 0.7) would imply less reabsorption of strontium in the kidney tubule compared to calcium. The argument for the relationship is somewhat torturous, but erudite. The reader is referred to Comar's exposition for details.

Direct measurements of renal clearance and reabsorption were made in U.K. children (Arneil 1967) using samples of blood and urine and activation analysis techniques. The ratio strontium/calcium was higher in the urine than in the plasma in all but one case. Reabsorption of calcium in the renal tubules was calculated to be about 99%, while there was less reabsorption of strontium by about 3% to 5% and thus more strontium in the urine.

Della Rosa, Smith, and Stannard, at Rochester (1961), did a full study of renal clearance and tubular reabsorption of calcium and strontium in trained dogs. They found, using endogenous creatinine to determine glomerular filtration, that ^{85}Sr cleared from the plasma at an average rate of 0.91 ml/min, while ^{45}Ca cleared at a lower rate, about 0.17 ml/min. Tubular reabsorption of calcium was about 99%, i.e., almost complete, while that of strontium was lower, about 97%. These processes can account for the discrimination between strontium and

(a) This seems very simple in view of today's sophisticated work in membrane biophysics. Active calcium transport in membranes remains under intensive study. It is a pity that the powerful tools of current membrane work were not available when this work on discrimination factors was most active. The problems should be re-examined in a good membrane biophysics laboratory.

calcium in the kidney with the difference in reabsorption probably being the most important.^(a)

Work in the United Kingdom (Shimmins et al. 1967) concludes that a factor of 3.34 exists in the kidney in favor of strontium over calcium excretion. This research used the double-tracer method and human patients. They consider that the effect may reside in differences in protein binding, but they did no renal clearance studies. The discrimination value was obtained from the slope of a line relating urinary specific activity to plasma specific activity as shown in figure 13.16.

FIGURE 13.16. The discrimination against the re-absorption of ^{85}Sr by the renal tubules obtained from the measurement of simultaneous plasma and urine samples; correlation coefficient, $r = 0.92$. No discrimination would yield the line marked $y = x$. (Redrawn from Shimmins et al. 1967. Reprinted with permission of Academic Press, New York, copyright 1967.)

It should be obvious that any quantities resulting from research under a given set of conditions may or may not apply to others. Of special importance is the age of the subject, as we have already seen. There appear to be other changes that occur with time and may reside in changes in the chemical form(s) of the elements as presented for excretion. Thus, Thompson and Hackett (1967) reported a study in rats receiving a single intraperitoneal injection of ^{45}Ca - ^{85}Sr . They were able to measure the amounts of each circulating in the plasma and the amounts excreted per day in urine and feces over a fifty-day period. The amounts decreased with time as expected, with the decrease in body burden but not in unison. First, the amount in urine fell off to a larger extent than the amount in feces, and second, the change with time was much less for ^{45}Ca , only to about one-half the initial, than for ^{85}Sr , which fell to about one-sixth of the initial level. The result was, of course, an increase in the urinary-fecal ratio with

(a) The ultrafilterable fractions of ^{85}Sr and ^{45}Ca in plasma were about the same. A difference between 99% and 97% reabsorption may seem small until one realizes that this alone could account for a factor of three in the final excretion. The Rochester work included also manipulation of plasma calcium levels by parathyroidectomy or parathyroid extract, metabolic acidosis, etc. None of these changed the ratio of excreted strontium to calcium.

time and also changes in the strontium/calcium, so that the observed ratio also changed with time, as seen earlier in figures 13.10 and 13.11. The explanation seemed to reside in considerable change in intestinal clearance with time with very little change in renal clearance. The figures are shown in table 13.8.

TABLE 13.8. Clearance Data

	After 7 days deposition (Group II)	After 47 days deposition (Group I)
<i>Calcium-45</i>		
Circulating in plasma*	0.51 ± 0.11	0.084 ± 0.022

Note that renal clearance of ^{85}Sr was about six times the clearance of ^{45}Ca at both seven and forty-seven days, in line with the postulated mechanism for the discrimination described earlier.^(a) Note also that intestinal clearance of both elements was higher than the renal clearance, and that it rises with time for both, rather than remaining approximately constant. The intestinal clearance of strontium increased more with time than that of calcium so that the ratio of intestinal clearance rates (strontium/calcium) went from about 1.5 at seven days to 3:2 at forty-seven days. This implies possible changes in the form of calcium and strontium in the blood to one more readily excreted via the intestine or less readily reabsorbed and that the process occurs to a greater extent with strontium. Such changes in physicochemical state of deposited radionuclides with time after deposition in blood and tissues have been noted on several occasions in this book. Note, for example, the work with polonium in chapter 4, the behavior long-term of the fission products and actinides in chapter 8, and some of the dilemmas of lung retention seen in chapter 9. For the case at hand, the authors propose as "not inconceivable" that calcium and strontium released from stable binding sites in bone or other tissues may exist in different chemical forms than when they entered the blood stream. From what we have learned in

(a) This was overall renal clearance, not the tubular-reabsorption figures.

this book, this author would propose that such a change is almost inevitable, particularly since, as the concentration decreases, the portion that is in radiocolloidal form may decrease considerably.

Another possibility involves the relative roles of the several compartments into which radionuclides are deposited from the blood stream.

There are many radionuclides (see earlier chapters) for which the ratio of urinary to fecal excretion changes with time. Probably most of these involve changes in the state of the nuclide as presented for excretion.

What information do we have on the relative retention of strontium versus calcium in bone? Here we must go back to the Metallurgical Laboratory work at Chicago (chapter 6). Norris and Kisielski (1948) reported that strontium is retained in skeleton to a lesser extent than is calcium, a "discrimination" of sorts, again in the direction of protecting the body from the more toxic element. Bauer, Carlsson, and Lindquist (1955), working in Sweden, were among the many who approached the general problem of metabolism of the two elements in bone and decided that the explanation for the lower retention of strontium resided in the discrimination processes we have already discussed, not in processes in bone itself. The skeleton seems unable to distinguish between the two elements, at least, grossly.^(a)

We thus have evidence that the three most important discrimination processes involve active biological processes. So also does the discrimination in the placenta. Can we conclude that Mother Nature developed these because she knew that humans would do something foolish like contaminating their environment with fallout? We cannot dismiss such ideas out of hand, but we can be less anthropocentric. In the case at hand, we need only remember that calcium is a key element in higher animals and is regulated zealously. Strontium neither occurs in organisms naturally in significant quantities, nor is it a key element. There are no homeostatic regulatory mechanisms for it. Hence, a difference in metabolism between the two is not surprising.

Many other mechanisms may allow discrimination between pairs of elements, e.g., relative ionic radii, relative charge, degree of hydration, relative half-life, any of which could yield a pseudodiscrimination. Also, some elements reside primarily within cells, others are primarily extracellular. Although these processes play a role in the behavior of radionuclides in the biosphere, they seem unlikely to be of controlling importance for the fallout nuclides in higher organisms.

The obverse of discrimination, viz., concentration, is a more universal phenomenon in the uptake of radionuclides in biological materials. As we have seen, these processes and the associated "concentration factors" are resident largely, but not only, in the way and extent to which the element participates in the metabolism of cells and tissues.

6. Practical Overtones

Much of the research described above was motivated by the desire to understand physiological and biochemical mechanisms. The basic concepts were formulated, however, as much to aid in the evaluation of hazard as to delineate mechanisms. We did need to know the transfer factors to the diet and from diet to humans (Wasserman et al. 1965) and have seen already that the postulates for the systems were met sufficiently well to satisfy their sponsors and all but the

(a) The extensive work on bone biochemistry fine tunes this statement a bit.

most concerned critics. There have been a few opportunities to test the results obtained through calculations based on data from environmental contamination and field research. We will consider some of these briefly in this section.

We can start with the fact that the OR for $^{90}\text{Sr}/\text{Ca}$ in desert animals was reasonably comparable to that in laboratory animals raised on commercial diets. Thus, observed ratios for Nevada desert animals were 0.2 for jack rabbits, 0.22 for cottontail rabbits, and 0.16 for kangaroo rats (Alexander, Nusbaum, and MacDonald 1956), compared to 0.35 in laboratory mice, 0.27 in laboratory rats, and 0.22 in laboratory guinea pigs (Comar, Wasserman, and Nold 1956). This is not perfect agreement, obviously. The OR values in the laboratory seemed to be fairly consistently higher than in wild animals of related species. Thus, we find that Cohn, Robertson, and Conard (1960), who examined the same data, suggested that the appropriate value for $\text{OR}_{\text{bone-diet}}$ would be 0.16 for the wild kangaroo rats in the Nevada desert compared to the commonly used blanket value of the OR of 0.25 for the experimental situation.

Research and field work in the Marshall Islands provided an excellent opportunity to test the ratio system and its parameters. A key discussion was presented by Cohn, Robertson, and Conard from Brookhaven (1960) at the Minneapolis symposium. As related in chapter 12, this group measured fission product uptake, distribution, and concentration in soil, plants, diet, aquatic forms, animals, and the Marshallese. To make an estimate of body burden of strontium from environmental contamination, they first used data on the $^{90}\text{Sr}/\text{Ca}$ ratios measured in rats collected on Rongelap. Since the ratio in the diet varied considerably in different foods, they had to use the ratio in soil as a surrogate for that in average diet. They extrapolated the environmental data to an expected equilibrium value and compared this to actual measurements in the animals. The extrapolation value, 924 pCi $^{90}\text{Sr}/\text{g Ca}$, was about twice the values measured by radiochemical analysis of animals that had lived on the island for two years following contamination, viz., 470 to 545 pCi $^{90}\text{Sr}/\text{g Ca}$. Did this mean the animals were not yet in equilibrium with the diet? Probably not, since animals analyzed at four years after contamination had closely similar ratios, viz., 443 ± 181 pCi $^{90}\text{Sr}/\text{g Ca}$. Therefore, other factors must have underlain the difference. The authors could not pinpoint any single factor but were inclined to attribute the problem to difficulties in determining the OR from soil to plants.

The measurements on the Marshallese were even less satisfactory. While estimates of body burden made by calculation from radiochemical analysis of urine agreed reasonably well with direct measurements made with the whole-body counter, the calculations from the $^{90}\text{Sr}/\text{Ca}$ ratios in diet varied widely. Examination of the input data from the diet provided an explanation. The diet of the Marshallese was far from constant, partly because of varying proportions of imported food such as "C" rations, partly because of varying input and composition of indigenous foods, and partly because of the discontinuous nature of their residence on Rongelap Island. Cohn et al. reviewed the various estimates of average dietary intake and decided that neither the Marshallese nor the animals had reached equilibrium (or a steady state), and reliable estimates from the environment could not be expected.

Much the same situation occurred in the determination of ^{137}Cs body burden in the Pacific islands, with the same factors responsible. With cerium, there is the added factor that its half-life is relatively short, and the calculation of steady-state value must be adjusted to consider radioactivity equilibrium as well as dietary input versus output.

The laboratory research indicated, while the field studies confirmed, that predictions of body or organ burden (e.g., skeleton) were not reliable if the system was not in equilibrium (or more precisely in a steady state). The environmental situation in the Marshall Islands was probably one of the least likely choices to meet that criterion. Was it better in other situations?

The 1966 international symposium on strontium metabolism held in Scotland in May 1966 came at a time when these questions were being considered very actively. Enough data had accumulated to provide reasonable chances to test the models based on experimental research. There were several summary papers there that we can utilize to approach the above question.

Joseph Rivera from the AEC Health and Safety Laboratory (HASL) played an important role, along with John Harley and others, in gathering the mountains of data on diets in New York City, Chicago, and San Francisco (chapter 12). Rivera (1967) compared the $^{90}\text{Sr}/\text{Ca}$ ratios to be expected from the diets to observations of ^{90}Sr vertebrae from accident victims in the same cities. He used three models: (1) one that assumed no change with age in replacement rate of skeletal calcium (f) or the bone-diet DF for strontium-calcium (which he designated as K); (2) one that assumed $f = 0.50$ and $K = 0.35$ during the first year of life and remained constant at $f = 0.035$ and $K = 0.25$ from that time on; and (3) a third model that assumed f and K varied with age from year one to year twenty over a range from 0.50 to 0.24 for f , and 0.35 to 0.13 for K , respectively. The predicted versus observed $^{90}\text{Sr}/\text{Ca}$ ratios for the period 1961 to 1965 agreed best for New York, poorest for San Francisco. If New York and San Francisco were combined, the second model worked best. However, the differences are difficult to take seriously. Choosing values of $f = 0.50$ and $K = 0.35$ clearly produced the best agreement between predicted and observed $^{90}\text{Sr}/\text{Ca}$ ratios during the first three to four years of life. Rivera was pleased in general with the figures obtained and concluded that ^{90}Sr levels in diet could predict average bone levels in children to about $\pm 25\%$ using the ratio method.

At the same symposium, Lenihan, from Glasgow, correlated ^{90}Sr levels in fetal bone with the concentration in milk (Lenihan 1967). The amount in bone after birth could be forecast from a knowledge of the concentration in milk for periods up to eighteen months. Both diet and bone figures were reported as $\text{pCi } ^{90}\text{Sr}/\text{g Ca}$. Bone and milk levels were rising with time over the period because of the gradual increase of ^{90}Sr in the environment. These, plus the comparison of observed to predicted levels, are shown in table 13.9A and B.

The agreement is reasonably close between observed and calculated values. Evidently, the rise in ^{90}Sr levels was gradual enough so that the fetal bone and maternal diet were in a quasi-steady state. This might not have held for adult bone, which accretes strontium more slowly than fetal bone.

An interesting exposition of some of the differences in environmental parameters between the USSR and the United States is given by Knizhnikov and Marei (1967). They point out that the daily intake of ^{90}Sr in the diet in the years 1963-1964 was considerably greater in the Soviet Union than in the United States; yet, the level of ^{90}Sr in human bone was about the same in various age groups in the two countries. They suggest two factors that might be responsible: (1) bread and grain represent the major source of dietary ^{90}Sr (and calcium) in the Soviet Union, whereas milk and dairy products play that role in the United States; and (2) fallout strontium deposited on growing crops is less soluble and less effectively absorbed in the human than the more soluble forms in dairy products.

The OR between bone from stillborns and maternal diet in the USSR work was about 0.053 over the period 1964-1965, considerably lower than that employed in any of the three models for U.S. diets by Rivera. That for the maternal skeleton to the natural diet was about 0.20. Their data showed a decrease in the discrimination coefficient (factor) for ⁹⁰Sr as a function of age in children, but it was very low for both stable strontium and ⁹⁰Sr in the fetus.

In this work, it was found also that another environmental factor could play a role, fluoride in drinking water. Some areas of the USSR, like some in the United

States have quite high natural fluoride contents in their drinking water. Knizhnikov and Marei (1967) found that the ^{90}Sr contents of human bones were lower in towns having such drinking water.

This work emphasized again the point made earlier in chapter 12 that predicted strontium bone burden will be different for diets with large components of milk and dairy products, on the one hand, versus grains and cereals on the other. If due cognizance is taken, the predictions are about equally satisfactory for Western and Eastern (Far-Eastern) diets.

Liniecki, from the Institute of Occupational Medicine at Lodz, Poland (Liniecki 1967), calculated ^{90}Sr concentrations in bones of adults by applying a power function for strontium retention. Again, all data were reported as $\text{pCi } ^{90}\text{Sr/g Ca}$ for both the diet and bone. Good agreement was obtained between predictions from diet and direct measurements in bone for New York City, Poland, and Great Britain.

Finally, we turn to a strictly research approach, i.e., not based on ambient environmental parameters, but pertinent nevertheless. This is a study by Rundo (1967) who was then at the U.K. Atomic Energy Research Establishment and is now at ANL in the United States. Healthy men were placed on a constant diet for twenty-one to thirty-two days that contained milk and tracer doses of the short-lived ^{85}Sr . Retention curves were best fitted by three exponential components rather than a power function.^(a) Experimental observations (whole-body counting) were in respectable agreement with the skeletal content predicted by the equations.^(b)

To a degree, all of the environmental and some of the experimental data considered above for strontium/calcium ratios have been incomplete in that they used a "shortcut." As Comar (1967) pointed out, the theoretically correct method would utilize either the ratio of the two stable elements or a double tracer such as the ^{85}Sr - ^{45}Ca . Comar addresses the question of the extent of error introduced by using the single tracer method, i.e., $^{90}\text{Sr}/\text{Ca}$. His analysis is based on pool sizes and timing. The rapidly exchangeable body pool for strontium and calcium is considered to be small (about 5 g of calcium and 1.7 mg strontium in man), but the urinary strontium and cesium come from it. The slowly exchangeable pool, which is bone, is larger (e.g., 1,000 g calcium and 345 mg strontium). Using data for ingested stable strontium in man, Comar concludes that, at ten days after a change in intake, the measurements would be in error by about 10%. Also, if the dietary intake has been more or less constant over a moderately long period, the "shortcut" method gives a good approximation. However, if dietary $^{90}\text{Sr}/\text{Ca}$ levels are changing rapidly, the calculated skeletal or body burdens will be in error and require several days to reach a new equilibrium or steady state after each such change.

Comar concludes that, in growing children or in the presence of changing dietary patterns, the double tracer or full-balance study may be required. This is, of course, not practical in most environmental situations. However, the question was left open as to how much the pool characteristics change under these circumstances. If they do not change very much, the "shortcut" may not be too misleading.

It was much the same story with cesium. The apparent lack of reliable correlation between it and potassium led to less emphasis on how well the body

(a) See chapters 7 and 8 for discussions of the pros and cons of these representations.

(b) The data were not reported as strontium/calcium ratios.

content of it could be predicted from parameters such as the cesium/potassium ratio. Langham and Anderson (1959, p. 42) engaged in the following calculation for ^{137}Cs from fallout: "If 1 mc/mile² gives 30 pc/g available soil potassium and the average surface deposition (December 1957) in the north temperate population belt was 36 mc/mile², the average ^{137}Cs level in people (assuming entry through the ecological cycle) would be $30 \times 0.03 \times 36 = 32$ pc/g K. People in the vicinity of 40°N-45°N (Washington State, the Dakotas, Minnesota, and Wisconsin) would average about 64 pc/g K."^(a)

Measured values of cesium in people during the fall of 1957 were surprisingly close to these calculated figures. However, Langham and Anderson considered it might be entirely coincidental and "could result from direct fallout on vegetation fortuitously making up for non-equilibrium of Cs^{137} with exchangeable soil potassium" (Langham and Anderson 1959, p. 42).

These authors, and many others, believed that direct deposition on vegetation played a central role in the entrance of cesium into the biosphere because of its high fixation in soil, its slow leaching rate, and the fact that the $^{137}\text{Cs}/\text{K}$ ratio in people and milk did not seem to be rising in relation to integrated fallout. They estimated that equilibrium levels in people who received the radionuclide by the soil route would not be reached in less than one hundred years because of the slow mobilization of cesium from soil. Since this mechanism would also predict a slow decline in cesium levels when testing ceased, and it was actually quite rapid, their skepticism about the agreement, noted above, may have been justified.

Much more on the behavior of cesium can be seen in the many reviews cited, including the one by Wasserman et al. (1965) in the Fowler book that considers most of the important radionuclides in fallout.

Work similar to that we have been quoting continued for many years but at a declining pace. As the fallout problems lessened, so did the pressure to test in the practical arena the ideas generated by the research. Nevertheless, the practice of reporting strontium and cesium as ratios to calcium and potassium, respectively, continued for a long time. This attests to the overall success of the ideas generated in the research in aiding evaluation of contamination of the environment and humans.

Perhaps the best evidence for this is seen in the 1977 United Nations report (UNSCEAR 1977). While some of the input figures are direct, i.e., not ratios, we find tables for strontium in milk given as the $^{90}\text{Sr}/\text{Ca}$ quotient, pCi/g Ca. The same is true for levels in bone in many countries and as a function of age.

By contrast, in the UNSCEAR documents, the levels of cesium are given sometimes as picocuries per liter of milk or as daily intake in picocuries and in other sections of the report as the $^{137}\text{Cs}/\text{K}$ quotient. The former are in tables where strontium and cesium are reported together. The latter appear in the section of the report on cesium where not only the amounts in diet but the transfer factors are given as ratios.^(b)

By the time of the 1982 UNSCEAR report, the quotient had disappeared completely and had been replaced by the linear parameter, Bq kg⁻¹ (UNSCEAR 1982). Naturally, there is no comment in the 1977 version as to why the quotient

(a) The 0.03 in the calculation comes from the OR for cesium calculated in figure 13.14.

The difference between the more northerly latitudes and the average was due to the more intense testing in this band, particularly the tests in Siberia.

(b) They called them, probably more properly, "quotients" rather than "ratios."

was considered worth keeping in use for so long, or why it is used in some contexts and not in others. Nor are there any remarks on its disappearance in the 1982 version. It is probably no longer needed. It may even be confusing in the context of environmental contamination around nuclear reactors, since here the chances of reaching equilibrium or a steady state are (happily) small. Also, the area involved is relatively small so that anything approaching uniform contamination of the diet or the environment is also unlikely. However, this is conjecture on the author's part and not based on any explanation given by the UN committee, since there was none.

The above discourse presents a few of the pitfalls as well as the successes in applying the ideas developed in the laboratory research to environmental contamination; i.e., the practical overtones. It is clear that the worst pitfalls are lack of equilibrium in the soil or diet and lack of a steady-state condition between the environment and the ultimate recipient. A glance at further work as seen, for example, in the selected publication list from Cornell (note 3) shows that research bearing on mechanisms thrived long after the major scare generated by fallout from weapons tests had subsided.

B. Aquatic Biology

There is ample general documentation in earlier chapters for the organizations, programs, and findings concerning the behavior and potential effects of radionuclides in fallout on aquatic organisms. No large experimental programs were designed specifically around the fallout problems produced in aquatic systems. The large observational programs already described (chapters 11 and 12) took up most of the time and talent. Nevertheless, enough strictly experimental work was done in the aggregate to warrant a short discussion separate from the large environmental and ecological enterprises.

Some of the effort concerned biokinetic behavior of radionuclides, and some concerned effects on aquatic biota. The former is primarily an extension of the vast observational studies already quoted. Since the results brought no real surprises, we will supply primarily samples with emphasis on earlier work. The work on effects extended the work with external radiation sources, alluded to earlier, to radionuclides in water. It will be described in compact form, partly because suitable reviews are available and partly because the bulk of the work was done in other parts of the world and must receive a lower priority in this review.

1. Uptake, Distribution, and Retention Under Laboratory Conditions

An early and useful insight into biokinetics in aqueous systems is contained in the report prepared by the Committee on Effects of Atomic Radiation on Oceanography and Fisheries of the U.S. National Academy of Sciences (NAS-NRC 1957) discussed in part in chapter 12. A full chapter therein is devoted to a summary of laboratory experiments on the uptake, accumulation, and loss of radioactivity from marine organisms (Boroughs, Chipman, and Rice 1957). There is also a careful analysis of the factors of importance to either laboratory or field research in chapter 7 (Krumholz, Goldberg, and Boroughs 1957).

The work shows that important factors governing the processes of concern are:

1. chemical composition of the organisms
2. concentration of the radionuclide

3. effect of the presence of one element on the uptake of another^(a)
4. specificity in organisms and tissues, based mostly on metabolic processes
5. ionic and osmotic conditions
6. stage in the reproductive cycle
7. presence or absence of molting
8. age and stage of growth
9. temperature
10. light
11. presence or absence of radiation effects.

Nearly all of the laboratory experiments described by Boroughs and colleagues took place at either the Fishery Radiobiological Laboratory of the U.S. Fish and Wildlife Service in Beaufort, North Carolina,^(b) where Rice and Chipman worked, or at the Hawaii Marine Laboratory of the University of Hawaii, where Boroughs worked. The experiments were classified according to the trophic level to which the organisms belonged.

Consider first the lowest trophic level, viz., plankton, etc. In twelve species of algae, the percentage of activity from strontium compared to yttrium, taken up from a culture medium with these in secular equilibrium, ranged from 100% strontium and 0% yttrium to 2.3% strontium and 97.7% yttrium in different species! There were also differences in the concentration factors relative to sea water among the twelve species.

By contrast, the uptake of cesium by nine species of marine algae was much more nearly uniform. Concentration factors ranged only from 1.2 to 3.1. No attempt is made to explain these differences, nor could such results have been predicted.

Considerable effort was devoted to the effect of concentration of the stable element in the medium on the percentage uptake of the radioelement. Most of the work concerned radioisotopes that could be presumed to be in ionic form in sea water, with the exception of ^{106}Ru , which forms colloids and particles in sea water.

At the second trophic level, work was done, for example, with larvae of the brine shrimp, *Artemia*; other shrimp; the blue crab; oysters; the bay scallop. All of these accumulated strontium rapidly from sea water, while cesium uptake was slower. The latter did not reach equilibrium for at least eighteen days, while the strontium uptake reached saturation in about eight days (see figures 4 and 5 in Boroughs, Chipman, and Rice 1957). The tissue distributions were also measured. The results were as expected from the experimental work with animals and the environmental studies on aquatic forms.

Fishes represented the highest trophic level. A considerable variety was studied to encompass the range between fast-swimming pelagic fish, such as dolphin, yellowfin, and skipjack, and ones like the sluggish bottom feeder, *Tilapia*. In some cases, the radionuclide was given to the fish orally in gelatin capsules to provide greater certainty regarding the dose. The sluggish fish with slow metabolic rates accumulated strontium considerably more slowly, and retention was also longer. It was clear that none of these fish took up more than a portion of the strontium and that discrimination could occur in these as in terrestrial

(a) A generalized version of the preceding discussion on the metabolism of pairs of elements.

(b) Later named Atlantic Estuarine Laboratory of the National Marine Fisheries Service.

animals and other organisms. Detailed analyses of the tissues revealed nothing unexpected.

It was clear that behavior of the radionuclides among species was much more uniform at this higher trophic level than in the algae. The chief differences at the highest trophic level resided in rates of movement tied to the level of metabolic activity.

Effective half-lives for several isotopes in several species of fish ranged from 6 to 841 days (see review by Rice and Baptist 1974). This is much less than the range of concentration factors. The considerable variability of these factors for several types of marine organisms can be seen in table 13.10. Note the large difference among ionic species for even noncalcareous algae.

TABLE 13.10. Approximate Concentration Factors of Different Elements in Members of the Marine Biosphere. The concentration factors are based on live weight.

Element	Form in sea water	Concentration in sea water (micrograms/l)	Algae (non-calcareous)	Concentration factors			
				Invertebrates		Vertebrates	
				Soft	Skeletal	Soft	Skeletal
Na	Ionic	10 ⁷	1	0.5	0	0.07	1
K	Ionic	380,000	25	10	0	5	20
Cs	Ionic	0.5	1	10		10	
Ca	Ionic	400,000	10	10	1,000	1	200
Sr	Ionic	7,000	20	10	1,000	1	50
Zn	Ionic	10	100	5,000	1,000	1,000	30,000
Cu	Ionic	3	100	5,000	5,000	1,000	1,000
Fe	Particulate	10	20,000	10,000	100,000	1,000	5,000
Ni*	Ionic	2	500	200	200	100	0
Mo	Ionic-Particulate	10	10	100		20

*Values from Laevastu and Thompson (1956)

Source: Reset from NAS-NRC 1957, chapter by Krumholz, Goldberg, and Burroughs, p. 74.

Obviously, these so-called concentration factors could obtain much of their variability from differences in the basic amounts of the different elements in the surrounding sea water. They could be quite different in some cases if the base line were fresh water. Nevertheless, this possibility does not account entirely for the tremendous range of values for different elements. Some of it could have been predicted from metabolic behavior, but not all.

Concentration factors for freshwater organisms determined in the relatively early environmental work on the Columbia River and White Oak Lake also show a wide range among the elements and among organisms (Krumholz and Foster 1957). More limited laboratory work on the goldfish and the guppy showed concentration factors ranging only from thirty for sodium to one

thousand for calcium; this probably indicates only the scarcity of experimental data at the time the academy's report was written.^(a)

In view of the relative constancy of the mineral content of sea water and the chances for large swings in the concentration of many elements in freshwater, the chances, given sufficient data, are considered good that concentration factors in marine organisms would be more constant than those in freshwater organisms (Polikarpov 1967). Indeed, Polikarpov takes the view that work with aquatic systems should lead to the establishment of principles and "regularities" in radioecology more readily than work with terrestrial organisms. The laboratory data did not provide much support for this hypothesis, but there may not have been enough data at the time.

At the Stockholm symposium on radioecological concentration processes held in 1966 and published in 1967 (Åberg and Hungate 1967),^(b) there was a collection of reports pertinent to our subject. The Polikarpov review cited above leads off the collection. In addition, the volume contains a sophisticated kinetic analysis of isotope exchanges by marine organisms by Polikarpov et al. (1967).^(c)

Nelson, from Oak Ridge (Nelson 1967), introduced the idea that ^{90}Sr -uptake by fish could be predicted on the basis of specific activities and half-lives rather than on the strontium/calcium ratio discussed in the previous section. He devised a fish-holding assembly that allowed the equivalent of whole-body counts and also measured tissue contents. He found that for predictive purposes the results of the specific activity approach and the ^{90}Sr -Ca ratio were about equal, but that was because the exposure concentrations were more or less constant. He held that the specific activity approach would be more reliable for prediction when the input conditions regarding either calcium or strontium were not constant. Incidentally, the biological half-life of strontium in white crappie flesh was only twelve to forty-eight minutes. Thus, the flesh would be very responsive to changes in environmental ^{90}Sr concentrations.

Workers from Chalk River reported experiments with goldfish on radiostrontium accumulation from food as compared to water and the effects of the alkaline earth content of food (both natural and synthetic) on the retention of ^{90}Sr . There was not a simple answer to the question whether fish would generally accumulate more ^{90}Sr from food or water (Ophel and Judd 1967).

Townesley (1967), from the University of Hawaii, measured ^{90}Sr and ^{89}Sr and concluded that the specific activity in the surrounding medium could be the controlling factor on their absorption by fish.

Häsänen et al., from Helsinki, built a "whole-body counter" for live fish and studied the biological half-time of ^{137}Cs in three species (perch, roach, and rainbow trout). The biological half-times increased with increasing age and differed among the species (Häsänen, Kolehmainen, and Miettinen 1967).

(a) The work of Prosser et al. (1945) and Prosser, Hagen, and Grundhauser (1947) on goldfish done at Chicago under the auspices of the Metallurgical Laboratory was quoted prominently. They used sodium, strontium, and barium-lanthanum. Again, we must salute the vision of the early workers as discussed in chapter 11. It is rumored that they received a bit of twitting for fooling around with goldfish, especially when fission products were scarce!

(b) The bibliography of the papers cited at this symposium can provide a useful overview of what was going on at the time.

(c) The data were largely from natural environments, but the analysis was a research contribution in itself.

Van der Borcht and Van Puymbroeck (1967), from Mol, Belgium, produced evidence for active transport of alkaline earth ions in freshwater gastropods. There were also experiments with chromium in crabs, radioiron in marine diatoms, ruthenium in mussels, zinc in crabs and oysters, etc., which produced results like those we saw in environmental work.

Additional work can be characterized by even more selective samples. The study of ion scavenging by the eastern clam and quahog by Andrews and Warren (1969), cited briefly in an earlier section, provides an excellent example of work that can be done handily in a laboratory aquarium. The initial problem was that the animals seemed to fix greater quantities of various radionuclides than they retained. Using ^{131}I , ^{85}Sr , and ^{59}Fe , Andrews and Warren showed that the difference, as expected, resided in the large amount taken into the organism and incorporated with considerable concentration en route into the feces. Thus, both animals functioned to remove ambient concentrations from solution or suspension in the water and to transfer them to deposits on the laboratory equivalent of the ocean floor. There were slow and fast components in the rate at which the organisms depleted the sea water, and they differed. The slow component was more marked (i.e., slower) in the quahog for ^{59}Fe and ^{131}I , while for ^{85}Sr it was the clam that was much slower. The comparison of iodine and strontium is shown in figure 13.17A and B.

FIGURE 13.17A. Depletion curves for relative activities (Rel. Act.) of ^{131}I from sea water by bivalves. (Redrawn from Andrews and Warren 1969. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1969.)

FIGURE 13.17B. Depletion curves for relative activities (Rel. Act.) of ^{85}Sr from sea water by bivalves. (Redrawn from Andrews and Warren 1969. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1969.)

Again, and despite Polikarpov's contention that the aquatic environment should be relatively uniform regarding the behavior of radionuclides in organisms, we see unexpected differences between elements and between species, even as closely related as the clam and quahog.

Slightly later, we find mixed in with the observational work reported at the Third National Symposium on Radioecology held at Oak Ridge in 1971

experimental work on such questions as the effect of temperature on retention of radiocesium by rainbow trout done by workers at Colorado State (Gallegos and Whicker 1971), the uptake of phosphorus by rooted aquatic plants (Schults and Malueg 1971), the relative accumulation of soluble and particulate radionuclides by estuarine fish (Hoss and Baptist 1971), the biological half-lives for zinc and mercury in the Pacific oyster (Seymour and Nelson 1971), and the effect of calcium concentration on accumulation of ^{45}Ca by developing Coho salmon eggs and fry (Olson 1971).

The work with temperature in trout was built around the question of how the water temperature and the weight of the fish, which depended in turn on the availability and type of food in natural habitats, might influence the concentration of fallout radionuclides in the fish. Radiocesium was chosen as the test nuclide since primary interest centered on the soft tissues that might become food for humans. There was a clear relation between both temperature and weight, as a "weighted average weight/temperature interaction term," for radiocesium retention. The results implied that both maximum uptake and maximum retention would be achieved at water temperatures that were optimal for food production and consumption and thus growth of the fish—not surprising.

The work with rooted aquatic plants came from the Pacific Northwest Water Laboratory in Corvallis, Oregon, and was only indirectly a result of fallout problems. The plants used were of the type that have developed into real nuisances in many small bodies of water and waterways. The purpose was an evaluation of the cycling of radiophosphorus between sediment and the water medium, a variation of the problem we have encountered in other connections regarding "food" (in this case material absorbed through the roots embedded in the sediment) compared to direct absorption from the surrounding medium. A double tracer, ^{32}P versus ^{33}P , allowed separation of the pathways. There was higher uptake by the foliage immersed in the surrounding water than via the roots immersed in the bottom sediments, and very little of the latter was transferred down to the root medium. Thus, the source of nutrient could be earmarked as primarily water.^(a)

The work on estuarine fish (Hoss and Baptist 1971) came from the National Marine Fisheries Service at Beaufort, North Carolina. These fish were a natural candidate for laboratory study since conditions in estuarine waters can change rapidly. Hoss and Baptist looked at ^{65}Zn and ^{144}Ce , presumably in ionic form and ^{51}Cr in particulate form. The typical estuarine fish absorbed little of the radionuclide in particulate form except by surface adsorption; also, the presence of sediment reduced the uptake of ^{65}Zn and ^{51}Cr because of their adsorption on the sediment particles. The results suggest that, in these estuarine environments, swallowed water is a more effective pathway than ingested food, but this generalization can be modified by changes of conditions.

The biological half-life of ^{65}Zn and of mercury in the oyster (Seymour and Nelson 1971) was determined in a laboratory aquarium at the University of Washington, College of Fisheries. Average biological half-life was different in different seasons by a factor of over two. The calcium study that also came from the University of Washington (Olson 1971) found that the radioisotope accumulated in inverse proportion to the amount of stable calcium present.

(a) In nature, the bottom sediments may build up radioisotopes, but we are talking here of normal plant nutrition in an aquatic milieu.

Of some interest to those accustomed to the multiexponential retention equations seen in most animal experiments and described also for some aquatic systems is work by Cutshall (1974) from the School of Oceanography at Oregon State University, which considered uptake and loss of ^{65}Zn by Pacific oysters. Both processes were well described by a single first-order equation, which implies "single compartment" isotope substitution kinetics. The constants estimated from either intake or loss were roughly comparable. Would that the systems were always as simple as this one appears to be.

Each laboratory with major field programs had occasion to check out specific points in an aquarium or a pool. It started at Hanford, as described in chapter 11, and grew into most of the other laboratories. Most of the generalizations made earlier concerning aquatic ecosystems were confirmed by the laboratory investigations and made more quantitative.

The fact that radionuclide-organism interactions are much different in sea water than in fresh water was amply confirmed. Perhaps the largest surprise was the persistence of very individual kinds of behavior among organisms and among radionuclides. Going to the laboratory did not, as might have been expected, greatly reduce such differences. They could not, therefore, be attributed to "unknown factors" in the environment, or at least the same "unknown factors" operated under laboratory as under natural conditions.^(a)

2. Effects on Aquatic Biota

Most of the research information on *effects* of fission products and other components of fallout on aquatic organisms has perforce been by laboratory experiment. Fortunately, except for a few local areas (see chapter 12), concentrations in the aquatic environment did not reach levels that would deliver significantly deleterious doses. Most of the early work addressed fish, their eggs or embryos, and used external x-ray or gamma-ray sources as described in chapter 11. We might add that succinct summaries can be found in the chapters by Donaldson and Foster (1957) and Krumholz and Foster (1957) in the NAS-NRC report cited in the previous section.

Work with radionuclides in water was not reported with any regularity until the late 1950s, except for the early reports on goldfish done at the Metallurgical Laboratory by Prosser (1945) and Prosser, Hagen, and Grundhauser (1947). For many years, the reports came primarily from the USSR, the United Kingdom, and Japan. The results were brought together in an important report prepared by panels of the IAEA that met periodically from 1970 to 1974 (IAEA 1976). Table 13.11 gives a more or less chronological overview of the work done, arranged by radionuclide and showing the organisms tested, the concentrations studied in the experiments, and the effects seen or looked for but not seen.

The concentrations at which positive effects appear are sometimes quite low and hark back to the admonitions of Polikarpov cited in chapter 12. It would be a major undertaking to calculate the associated radiation doses, and even if these were calculated, we could not be sure of their adequacy. Suffice it to say that the investigators did not find major differences in apparent radiosensitivity between the aquatic organisms tested and the more commonly studied terrestrial forms. It should be realized that much of the work involved eggs or

(a) This should not be interpreted as indicating that better data and greater consistency did not result from the laboratory studies; only that the differences continued to be real and were not wiped out universally by the "controlled experiment."

TABLE 13.11. Summary of Experimental Studies on the Effects of Radionuclides in Water on Aquatic Organisms

		(Positive Effect: ● or ) (Negative Effect: ○ or )							
		Concentration of Radionuclides * ($\text{Ci} \cdot \text{l}^{-1}$)							
Investigators		10^{-12}	10^{-10}	10^{-8}	10^{-6}	10^{-4}	10^{-2}	1	Types of Effects
1958. Lebedeva, Sinevid	^{90}Sr ^{90}Y								Shortened the life-span of adult individuals of <i>Daphnia magna</i>
1958. Telichenko									Delay in embryonic development of fish eggs (anchovy)
1961. Polikarpov, Ivanov	^{90}Sr ^{90}Y								Increase in the mortality rate of embryo of fish eggs and tendency to be smaller in size of young fish was observed
1962. Polikarpov, Ivanov	^{90}Sr ^{90}Y								Decrease in cell division in gastrula stage and chromosome aberration of fish eggs (anchovy, stone perch)
1962. Polikarpov, Ivanov	^{90}Sr ^{90}Y								Increase in malformation rate of fish eggs (anchovy, mullet, green wrasse, horse mackerel)
1964. Fedorov et al.	^{90}Sr ^{90}Y								Increase in malformation rate of fish eggs (plaice, <i>Pleuronectes platessa</i>)
1964. Brown, Templeton	^{90}Sr ^{90}Y								No significant increase in mortality or in the production of abnormal larvae (brown trout, <i>Salmo trutta</i>), (plaice, <i>Pleuronectes platessa</i>)
1966. Neustroev, Podymakhin	^{90}Sr ^{90}Y								The rate of development of the egg was the same as the control up to the stage of one-third development of the yolk sac (Atlantic salmon, <i>Salmo salar</i>)
1966. Kulikov et al.	^{90}Sr ^{90}Y								Morphological abnormalities, delay in development and mortality (eggs of the fresh water mollusc, <i>Lymnaea stagnalis</i>)
1968. Shekhanova, Pechkurenkov	^{90}Sr ^{90}Y								Non-developing larvae appeared in developing eggs of the loach
1970. Hiyama, Shimizu, Suyama	^{90}Sr ^{90}Y								Sharp decrease of the rate on attaining to pluteus stage (see urchins, <i>Pseudocentrotus depressus</i> , <i>Anthocardia crassispina</i>)
1970. Hiyama, Shimizu, Suyama	^{90}Sr ^{90}Y								Normal rate of hatching and malformation of eggs (<i>Mylio macrocephalus</i> and <i>Rudaris ercodes</i> in sea water)
1970. Egami et al.	^{90}Sr ^{90}Y								Normal rate of mortality and abnormality of the embryo (fresh water killifish, <i>Oryzias latipes</i>)
1970. Egami et al.	^{90}Sr ^{90}Y								Effect on gonad was found in fish, exposed in contaminated water, continuously 70 days after hatching (fresh water killifish, <i>Oryzias latipes</i>)
1970. Egami et al.	^{90}Sr ^{90}Y								Damage on seminal glands in fish, exposed 15-30 days (fresh water killifish, <i>Oryzias latipes</i>)
1973. Kosheleva	^{90}Sr ^{90}Y								Egg mortality during the time of incubation was at the control level in the Atlantic salmon (<i>Salmo salar</i>)
1972. Nelson	^{90}Sr ^{90}Y								Significant increases in abnormal larvae (Pacific oyster, <i>Crassostrea gigas</i>)
1972. Tsytugina	^{90}Sr ^{90}Y								Significant increase of chromosomal breakages was found in the ruff (<i>Scorpaena porcus</i>)
1971. Guthrie and 1973. Brust	^{90}Sr ^{90}Y								The testes and ovaries of adults were atrophied when larvae of <i>Aedes aegypti</i> and <i>A. atropalpus</i> were reared in radioactive water
1972. Scott									No significant differences on rainbow trout during embryogenesis
1973. Strand et al.	^{90}Sr ^{90}Y								No decrease in the percentage of dividing cells was detected in the investigated development stages. In variants with $2 \times 10^{-8} \text{ Ci} \cdot \text{l}^{-1}$, there was a reliable increase in the frequency of chromosomal aberrations, beginning with the epithelial blastula stage (<i>Salmo salar</i>)
1973. Migalovskaya	^{90}Sr ^{90}Y								No influence on population density in a population of a copepoda (<i>Tigriopus californicus</i>) kept in radioactive water for several years
1965. Williams, Murdoch	^{137}Cs								No visible abnormalities on the developing eggs and larvae (mummichogs, <i>Fundulus heteroclitus</i>)
1967. White et al.	^{137}Cs								No effect on the reproduction of <i>Artemia salina</i>
1969. Hallopeau	F.P., ^{137}Cs								

TABLE 13.11. Continued.

		(Positive Effect: ● or ) (Negative Effect: ○ or )								
		Concentration of Radionuclides * ($\text{Ci} \cdot \text{l}^{-1}$)								
Investigators		10^{-12}	10^{-10}	10^{-8}	10^{-6}	10^{-4}	10^{-2}	1	Types of Effects	
1973 Kosheleva	F.P., ^{137}Cs								Considerable number of deaths were observed in the Atlantic salmon (<i>Salmo salar</i>) when the eggs were exposed to radioactive water	
1973 Migalovskij	^{144}Ce									
1971 Mashneva	F.P.								Damage at early stages of developing eggs of carp and <i>Coregonus peled</i>	
1972 Nelson	^{61}Cr or ^{66}Zn								Significant increases in abnormal larvae (Pacific oyster, <i>Crassostrea gigas</i>)	
1973 Havlik, Robertson	^{226}Ra								Photosynthetic oxygen production in fresh-water phytoplankton was sharply reduced by 24 hours exposure to a ^{226}Ra concentration of $3 \times 10^{-8} \text{ Ci} \cdot \text{l}^{-1}$	
1970 Akita, Shiroya	HTO (tritiated water)								50% attainment to pluteus (red sea urchin, <i>Pseudocentrotus depressus</i>)	
1970 Akita, Shiroya	HTO (tritiated water)								50% attainment to pluteus (violet sea urchin, <i>Anthrocidaris crassispina</i>)	
1970 Etoh, Ueno, Ichikawa	HTO (tritiated water)								Slight decrease of the rate of hatching (fresh water killifish, <i>Oryzias latipes</i>)	
1969 Buggeln, Held	HTO (tritiated water)								Reduced percentage of germination of the asexually produced spores (<i>Padina japonica</i>)	
1970 Blaylock et al	HTO (tritiated water)								No effects on embryo development of <i>Cyprinus carpio</i>	
1973 Walden	HTO (tritiated water)								No effects on embryo development of <i>Gasterosteus aculeatus</i>	
1973 Erickson	HTO (tritiated water)								No significant effect on mortality growth, male characters, behaviour and thermal death of the guppy fish, <i>Lebistes reticulata</i>	
1974 Ichikawa, Suyama	HTO (tritiated water)								Decreases in hatchability were observed and $10 \text{ Ci} \cdot \text{l}^{-1}$ effects were noted on body shape and eye diameter of larvae of two species of marine fish (<i>Paralichthys olivaceus</i> and <i>Fuguiphobies</i>)	
1972 Fedorova	^{14}C								Increase of malformed larvae of <i>Coregonus peled</i> , when $\text{NaH}^{14}\text{CO}_3$ was added to the water seven days after fertilization	
1972 Tsytugina									Significant increase of chromosomal breakages was found in the ruff (<i>Scorpaena porcus</i>)	

Note: * It is important to realise [sic] that the quoted concentrations do not indicate directly the dose received by organisms and/or organs.

embryonic stages of development of the aquatic forms and should thus be compared to developmental stages of terrestrial organisms.

The broad review by Rice and Baptist (1974) already mentioned gives a tabular summary of the radiosensitivity of aquatic organisms in terms of LD_{50} doses. Since it concerns only x- and gamma radiation from external sources, the table is not reproduced here but should be useful to those interested.

In addition to the processes listed in table 13.11, there have also been studies on genetic effects in aquatic forms (with equivocal results), the possibilities for repair of radiation damage, behavioral and metabolic stimulation, and environmental factors of importance in determining effects.

Included in the same IAEA report is detail on a chronic feeding experiment with yearling rainbow trout performed at Hanford over a several-year period. The results are shown as table 13.12:

TABLE 13.12. Effect of Chronic Ingestion of ^{32}P , ^{90}Sr - ^{90}Y , or ^{65}Zn on Yearling Rainbow Trout, *Salmo gairdneri*. Work at Hanford.

	Treatment $\mu\text{Ci}\cdot\text{g}^{-1}$ fish (day)	Duration of feeding (weeks)	Growth depression	Significant mortality	Leucopenia	Gut damage	Concentration at end of feeding ($\mu\text{Ci}\cdot\text{g}^{-1}$ wet)

Growth depression, leucopenia, gut damage, and significant mortalities were seen in trout fed $0.5 \mu\text{Ci } ^{90}\text{Sr}$ - ^{90}Y per gram daily for twenty-one weeks (a fairly large dose). Levels of 0.05 and $0.005 \mu\text{Ci/g}$ did not produce effects that could be measured. Phosphorus-32 was equally, if not slightly more, effective, while ^{65}Zn produced only leucopenia at the highest dose. If one considers that the highest dose resulted in levels of body burden of over 2,200 μCi of ^{90}Sr - ^{90}Y in a trout weighing 300+ g, we must be impressed by the relative radioresistance of these fish. However, truly long-term effects were not investigated.^(a)

The IAEA panels concluded that the most radiosensitive aquatic organisms are teleost fishes, particularly developing eggs and young of certain species. The most important effects are those that might operate at the population level such as fertility, fecundity, development, etc., but it seemed clear from the researches reported and the conclusions of the expert panels that doses needed to bring about significant changes would be moderately high, considerably above anything present in the current ambient environment. Thus, the research did not materially alter the conclusions from the environmental work quoted in chapter 12. However, it made them more secure.

Despite this relatively optimistic conclusion, it is not difficult to find large areas of aquatic biology that would benefit by more extensive and more penetrating research efforts on effects of radionuclides.

C. Plants and Plant-Soil Interrelationships

Research on the uptake, translocation, and retention of fission products and actinides by plants of many kinds began well before fallout occupied center stage. It was carried out primarily around the major production sites, Hanford

(a) The stimulus for long-term follow-up did not spread rapidly from the terrestrial animal realm to aquatic forms.

and Oak Ridge. The field work was described in chapter 11, and the fact that controlled laboratory work was needed and done was alluded to. In a previous section of this chapter, the role of early research at Hanford on plants in connection with the metabolism of pairs of elements was described. All of this, as well as the later work at the Savannah River facility, merged gradually into the developing research programs aimed at the problems of fallout. Since the projects form a continuum, it is difficult to earmark given pieces of work as having been directed specifically toward the problems of fallout. Therefore, we will discuss the pertinent work that could apply to fallout problems without splitting hairs regarding its motivation.

The U.S. installations most involved in either kinetic studies or work on effects, or both, include in addition to Hanford, Oak Ridge and Savannah River, the U.S. Department of Agriculture, University of California at Los Angeles and at Berkeley, Los Alamos, Brookhaven, and the UT-AEC Farm. There was also significant work abroad, especially in the United Kingdom and the Soviet Union. We will consider first some of the earlier work that more or less set the pattern and then studies that applied respectively to soil and soil chemistry, soil-plant interrelationships and distribution within plant parts, foliar deposition and absorption, and biological effects. In each case, we will attempt to identify contributions with the laboratory of origin.

1. Earlier Work

Probably the first identifiable reports on the behavior of fission product isotopes and actinides in plants came from the work of Jacobson and Overstreet at Berkeley during the Manhattan Engineer District (MED) days. This concerned uptake of several elements by the roots of barley and dwarf pea plants. The reports, produced first as an in-house document of the MED in 1945, and in 1947 as a publication in the open literature, were discussed briefly in chapter 6. The phenomena of ion exchange were just beginning to be utilized in ion exchange resins elsewhere in the MED and may have influenced the thinking on plant exchanges, although it could have easily been vice versa. At any rate, exchange reactions and metabolic processes were considered seriously. This early plant work pointed to the presence of similar exchange phenomena in the soil.

In the early 1950s, the Hanford annual reports began to carry periodic items on the uptake and translocation of fission products by plants (see, for example, Rediske and Selders 1952; Rediske, Cline, and Selders 1955).^(a) The plants were cultivated in nutrient solutions that were continuously aerated. Strontium-90, ^{90}Y , ^{137}Cs , and ^{131}I were added as tracers to the nutrient solutions. Uptake to beans was found to be proportional to concentration over a wide range. The accumulation of yttrium and iodine increased with increasing acidity, but that of cesium was little affected by pH, while that of strontium decreased with increasing acidity. Explanations were based on the tendency (or lack of it) for insoluble particles or complexes to be formed. Differences were found among species as just described for aquatic organisms. It was marked with cesium and yttrium, not so marked with strontium. Bean and tomato were consistently more efficient in taking up the radionuclides than wheat or Russian thistle. In none of the species did the fruit concentrate any of these four isotopes to any marked degree.

(a) The second reference cites several other progress reports issued in the intervening years.

In the 1955 Hanford report, ^{140}Ba , ^{106}Ru , and ^{239}Pu were added to the isotopes listed above. Concentration factors (leaves/soil) were determined for several soils and several species. Those for strontium were always the highest for barley, but for some other species that for ^{137}Cs was comparable or even a little higher. These relatively pioneering data are shown in table 13.13A and B.

TABLE 13.13A. The Concentration Factor (Conc. of Isotope in Leaves/Conc. of Isotope in Soil)* of Several Isotopes as Determined by the Neubauer Seedling Test Using Barley Grown in Representative Soils

Source: Modified slightly from Rediske, Cline, and Selders 1955.

Thus, we see again that the patterns of uptake are element-specific and species-specific and considerably affected by the composition of the medium, in this case soil. Note that in only a few instances are the concentration factors for these plants higher than unity. In general, they were well below unity, quite in contrast to those we saw for aquatic biota in table 13.10. The radionuclides are much less available from soil than from water.

This early Hanford work was presented, in part, at the first Atoms for Peace Conference in Geneva (Rediske and Hungate 1956). Considerable point was made there of the increase in absorption with increase in concentration.

Meanwhile, comparable pioneering experimental work was being done by the budding radioecology group at Oak Ridge National Laboratory (see chapter 11).^(a) We saw some of their work involving inoculating trees, and their survey work on the White Oak Lake bed in chapter 11. A more or less typical example of their attack on some of the problems just described can be seen in work by Auerbach and Crossley (1958), which was summarized at the second Atoms for Peace Conference in Geneva, Switzerland. It did not utilize nutrient solutions but used instead the natural soils of the White Oak Lake bed. Since specific crops were grown in specific plots, and a careful experimental pattern was applied, the work can still be classified as research. This work did not report concentration factors, partly because the base-line for the soils was rather tenuous. They showed real differences among the parts of plants and very large differences among the isotopes measured. These are illustrated in table 13.14.

The Oak Ridge work, like that described above, indicated discrimination factors near unity, with some variation among plant parts. They also studied the

(a) Plant work at the UT-AEC farm came somewhat later.

TABLE 13.14. Work on Corn Grown in White Oak Lake Bed, Oak Ridge, Tennessee. Mean Concentrations of Elements^(a) in *Zea mays*.

Element (per 100 g)	Leaf	Husk	Grain	Cob	Stem	Flower	Least significant difference
Sr ⁹⁰ (10 ⁻³ μ c)	39.7	6.3	2.5	4.4	12.1	28.4	11.00

Source: Modified slightly from Auerbach and Crossley 1958.

strontium/calcium ratios and found relatively little discrimination against strontium, even though the calcium level in the soil (corn plot) was moderately high. Later work at the UT-AEC Farm on field crops yielded comparable results.

This work with plants led to the same emphasis on strontium as the key radionuclide from the standpoint of hazard as came out of the animal experiments. Although the concentration factors were all much lower than in animal or aquatic systems, strontium was, in general, at or near the top in actual concentration. Besides, it had a long half-life and a low maximum permissible concentration (MPC) in humans. It cannot be said that the high uptakes and retention of strontium were expected to the same extent as in animal systems with their large bony structures. Indeed, it might have been expected that plant systems would show a different pattern, particularly in research where individual variables could be controlled. But they did not.

2. Concentration of Plant and Soil Work on Fallout Problems

While the earlier work was clearly applicable to the radionuclides in fallout, it was quite general in purpose. As the fallout controversy heated up, more and more research on plants and soils was overtly correlated with it. Experimental work was done in many more laboratories than took part in the earlier work. Among these was the Atomic Energy Project at UCLA whose involvement with weapons testing we have already seen. The University of California, Los Angeles, began greenhouse experiments very early, and even now some residuals of the work continue to be reported. Work on soil also expanded. In addition to UCLA and Hanford, the laboratories included Los Alamos, the USDA, and laboratories in the United Kingdom and the Soviet Union.

While the research forms a continuum, it is useful to segregate our discussion and consider in turn soils per se, soil-plant interrelations and movement within plants, the role of foliar deposition and absorption, and finally, effects.

a. Soils

It was soon apparent, as the data in table 13.13A showed, that soil type could exert a large influence on plant uptake. Research on what was going on in the

soil attracted chemists and agronomists. The idea of fixed versus exchangeable portions of the soil constituents is threaded throughout the research (note, for example, the inclusion of "cation exchange capacity" for the soil types listed in table 13.13A).

A handy compendium of what earlier research on soils in various laboratories was revealing is found in the first four papers in the Minnesota symposium. Alexander, Hardy, and Hollister (1960) from the USDA, HASL, and AEC Headquarters, respectively, put special emphasis on strontium in soil at a variety of locations. This was mostly observational, but the effects of depth, amount of precipitation, and other environmental factors were investigated. The next paper concerning work done at Berkeley (Hanson, Vidal, and Stout 1960), considered the physicochemical composition of soil and its influence on the behavior of both naturally occurring and manmade radioisotopes. Menzel (1960), from the USDA, studied the effects of soil amendments on availability of various isotopes. Addition of lime, gypsum, fertilizers or organic matter, in reasonable doses, had only moderate effects on availability of ^{90}Sr . The effects were larger on some of the other fission products, but the importance of these was smaller because of the lesser hazard of the radionuclides concerned (i.e., ^{137}Cs , ^{144}Ce , and ^{106}Ru).

The fourth paper in the soil series, also from the USDA, included much about soil-plant interrelationships (Fried and Heald 1960). It provided insight into the general thoughts about soil mechanisms, including the idea that there were ions in solution in soil, ions fixed by chemical bonding, and ions attached to particles by adsorption. The relative contribution of each of these is influenced greatly by conditions such as pH, concentration of the elements, presence of other elements, differences in anions, etc.

Consideration of and research on the state of radionuclides in soil permeates much of the UCLA ecological work beginning with the early reports on the Trinity site (chapter 12). There were many observations on the relative fixation of different radionuclides. Laboratory work was reported as early as 1953. Neel et al. (1953) studied five isotopes, ^{90}Sr , ^{137}Cs , ^{106}Ru , ^{144}Ce , and ^{90}Y , in five different California soils. In further work, the fractions in soil of water-soluble nonexchangeable ^{90}Sr , ^{89}Sr , ^{91}Y , ^{106}Ru , ^{137}Cs , and ^{144}Ce were measured in a laboratory experiment and found to be quite different from each other (Nishita, Kowalewsky, and Larson 1954). Interestingly, the exchangeable fraction of ^{89}Sr was found to be greater than that of ^{90}Sr (mechanism?) and both of these were higher than ^{137}Cs and much higher than the other nuclides. The reverse was, of course, true for the nonexchangeable fraction.

A good review of this and related work at UCLA with soils and plants can be seen in a summary report (Nishita and Larson 1957). Other research at UCLA bearing primarily on soil reactions concerned the influence of stable cesium and potassium on the reactions of ^{137}Cs and ^{42}K in soils and clay (Nishita et al. 1959, 1960), reactions of tungsten in soil and its uptake by plants (Romney and Childress 1961), and a general review in 1965 (Nishita, Romney, and Larson 1965). There was also some work on chelation (see next section), and work on plutonium in soils. It began, as we have seen, in connection with the studies around the Trinity site; but true research came considerably later.

Research on the relative exchangeability and nonexchangeability of ^{90}Sr in soil and its importance to plant uptake was followed further at the Department of Agriculture (Roberts and Menzel 1965). This was a greenhouse experiment with four soil types obtained from North Carolina. The percent of

nonexchangeable ^{90}Sr varied from 11.9 to 50.3, a not inconsiderable factor to reside in the soil alone.^(a)

Probably the "purest" research involving interactions of radionuclides and soils came after the peak of activity in fallout research. It was concerned more with the problems of nuclear waste disposal and included the actinides to a greater extent than earlier work. Details are beyond our purview here. However, a glimpse of the kinds of work done can be gleaned from the first five papers in a special issue of *Soil Science* (132(1) July 1981) devoted to a multi-laboratory endeavor^(b) on radionuclides in soil. The five papers are listed below:

1. "The Interactions of Low-Level, Liquid Radioactive Wastes with Soils: Behavior of Radionuclides in Soil-Waste Systems." E. B. Fowler, E. H. Essington, and W. L. Polzer.
2. "The Interactions of Low-Level, Liquid Radioactive Wastes with Soils: Differences in Radionuclide Distribution among Four Surface Soils." E. H. Essington, E. B. Fowler, and W. L. Polzer.
3. "The Interactions of Low-Level, Liquid Radioactive Wastes with Soils: Interaction of Waste Radionuclides with Soil from Horizons of Two Soil Series." W. L. Polzer, E. B. Fowler, and E. H. Essington.
4. "Effect of Soil Type on the Extractability of ^{237}Np , ^{239}Pu , ^{241}Am , and ^{244}Cm as a Function of pH." H. Nishita, A. Wallace, E. M. Romney, and R. K. Schulz.
5. "Some Factors That Influence the Extractability of ^{239}Pu from Several Clay Minerals." H. Nishita and R. M. Haug.

The first three papers were from the Los Alamos National Laboratory, the other two were from UCLA (Laboratory of Nuclear Medicine and Radiation Biology, new name for the old Atomic Energy Project).

The types of complexing and various mechanistic aspects were emphasized. It was clear that the research showed considerably more sophistication in understanding the interactions of radionuclides with various soil components than in the 1950s and 1960s.

As part of the series of reports on fallout prepared by the NAS-NRC in the mid-1950s and early 1960s, known as the BEAR reports and cited in earlier chapters, there was one on the behavior of radioactive fallout in soils and plants. This review (NAS-NRC 1963) was prepared by M. H. Frere and R. G. Menzel from the USDA; Kermit Larson from UCLA; Roy Overstreet from the University of California, Berkeley; and R. F. Reitemeier, a soil scientist with the AEC Division of Biology and Medicine. In its survey section on soil reactions, the several processes were described briefly. A few general comments can be made:

- a. Because of the very low concentrations involved, adsorption of most of the ions of importance to fallout studies was found to be nearly complete. It would fall off at concentrations above about 0.01 times the saturation capacity of the soil.

(a) The fractions varied in different years; those given are for 1955. The range was lower in 1958.

(b) University of California at Los Angeles and at Berkeley, Los Alamos, and Savannah River.

- b. Removal (i.e., desorption) is difficult and may require very large volumes of water. Nevertheless, there is gradual leaching of the more mobile materials such as ^{106}Ru and ^{106}Rb to lower strata. Strontium is leached more slowly, while cesium and plutonium are still more tenaciously held.
- c. Complementary ions exert strong effects on adsorption. The order of replacement of soil materials is usually $\text{Li} < \text{Na} < \text{K} < \text{NH}_4 < \text{Rb} < \text{Cs} < \text{H} < \text{Mg} < \text{Ca} < \text{Sr} < \text{Ba} < \text{Fe} < \text{Al} < \text{La}$. No single exchange reaction appears sufficient to account for the phenomena.
- d. The effect of pH is not simple. High acidity or alkalinity result in decomposition of soil minerals, and less fission product adsorption occurs. Maximum adsorption of strontium seems to occur at pH 7 and 9, of cesium at pH 6 and above, of yttrium and cerium above pH 6 and of plutonium from pH 2.5 to 9.0.
- e. Clay is unique in some of its capacities for exchange. There are differences among clays.
- f. Organic matter that can be decomposed can reduce the uptake of strontium by soil.
- g. Mechanisms exist for more or less permanent fixation of portions of the radioisotope content of many soils.
- h. A result of all this is that practically never is all the radioactivity resident in a given soil available for plant uptake.

While there was considerably more work done on soil-radionuclide interactions, it is so intimately bound up with plant uptake and mobilization studies that we will postpone further discussion to the next section.

b. Plant Uptake, Soil-Plant Interrelationships, Distribution in Plants

Programs at several American laboratories concentrated on plant uptake and subsequent phenomena before, during, and after the climax of the fallout problems. Early work has already been mentioned. Studies concerned with the major sites and the more purely observational work have also been described (in chapters 11 and 12). Foliar deposition will be considered as a separate entity. Is there anything left? Indeed there is, as we will see.

The UCLA project was a prime contributor to the experimental work that followed the earlier Hanford and Oak Ridge landmark studies.

It became evident from "glasshouse" studies that strontium uptake clearly exceeded that of ^{137}Cs and ^{106}Ru in several species of plants (Neel et al. 1953), while uptakes of ^{144}Ce and ^{91}Y were negligible, all in conformation to the field work. There was also expansion of work on the effects of pH, concentration of stable carrier, of other ions, and even of temperature (Ehrler, Lange, and Hamner 1955; Ehrler, Romney, and Hamner 1955; Lange, Ehrler, and Hamner 1955; Romney et al. 1956; Goss and Romney 1957; and summaries by Nishita, Romney, and Larson 1965; and Nishita and Larson 1957). These experiments confirmed, extended, and made more quantitative the general findings already presented for less controlled conditions. They usually used only one radionuclide at a time and, of course, tested several plant species, but only one at a time, usually under optimal conditions for growth.

There was interest in whether or not the events noted in a single-generation experiment would extend over successive generations. This was approached by growing clover through fourteen successive cuttings under the influence of application of a calcium amendment aimed at suppressing strontium uptake

(Romney et al. 1960). There was some change with time, partly because the soil was initially low in calcium.^(a)

Some of the research was aimed toward finding ways to decrease or even prevent the uptake of the most hazardous radionuclides. Much of the work on addition of calcium, potassium, etc., had this as an objective as much as the strontium/calcium ratio and mechanisms. A new approach to this was through the possible effects of chelating agents (see chapter 19 for the agents and their application to therapeutic removal of radionuclides from animals and humans). At UCLA, Essington, Nishita, and Wallace (1961) tried several such agents, e.g., DTPA, HEEDTA, EDDHA (see chapter 19). The uptake of ^{91}Y and ^{65}Zn was increased, not a surprising result if we regard the chelation process as a solubilization process. This effect was, of course, in the wrong direction for suppressing uptake.

In much later work on the actinide ^{241}Am , (Wallace et al. 1976) there was ample evidence that DTPA could increase plant uptake significantly. The result was a discrimination ratio for the radionuclide of as much as seven instead of the normal ratio of unity or below. There were differences in detail among plants. These results were of scientific interest, but somehow the converse experiment of seeing if chelating agents would hasten the elimination of radionuclides from plant parts, i.e., the approach used in the animal work, did not get done. However, it was noted that even the solubilized americium was not readily translocated to the reproductive parts of the plants.

One of the primary conclusions from the UCLA research was that no matter how conditions were changed, the isotope showing greatest uptake and greatest potential hazard via the plant chain still was strontium. Thus, again plants did not differ from animals. The low capacity of plants to take up ^{91}Y , ^{106}Ru , ^{137}Cs , ^{144}Ce , etc., placed these in the category of "nuisance factors" compared to ^{90}Sr (Romney et al. 1957). Furthermore, no practical manipulation of soil characteristics had really significant effects on plant uptake rates except when a deficient soil was brought up to normal content of, for example, calcium, potassium, etc., or the soil was relatively infertile (Romney et al. 1959).

Work at Los Alamos on plant uptake has already been noted in connection with discrimination against strontium versus calcium at various calcium levels (figure 13.13). As described, Adams, Christenson, and Fowler (1965) looked at the influence of depth of cultivation on uptake of ^{137}Cs . While there were species differences, there was no doubt that deeper cultivation increased the fraction absorbed. Indeed, very deep cultivation resulted in nearly complete absorption. This highlights again the very important difference between field and laboratory since it is common in the laboratory experiment to mix the radionuclide quite completely with the soil. Cultivation in the field seldom approaches complete mixing to the depth of many plant roots.

The researchers also looked in some depth at the deposition and retention of radionuclides in different parts of the plants. Some of the results can be seen in the reviews cited above. Leaves tended to accumulate the most on the average. Stems tended to be about half as active as leaves, and other parts were still lower. Roots were sometimes quite high, probably because of their direct contact with the elements in soil. An example of the range of distribution among

(a) Later work with plutonium showed more clear-cut changes with time, as we will see presently.

the parts of plants of seven species and for six isotopes is given in table 13.15, taken from UCLA work.

TABLE 13.15: Distribution of Fission Products in Different Parts of Crop Plants

Plant parts	Dose in Soil $\mu\text{C/kg}$	Radioisotope

Such distributions changed in an absolute sense but not relative to each other when the nutrients came from water cultures rather than soil (much higher counts in each part from the water culture).

The relative order of plant uptake of fission products and plutonium defined by these many laboratory experiments was $^{89-90}\text{Sr} > ^{131}\text{I} > ^{140}\text{Ba} > ^{137}\text{Cs}$ and at much lower levels $^{106}\text{Ru} > ^{144}\text{Ce} > ^{91}\text{Y}$ and $^{147}\text{Pm} > ^{239}\text{Pu}$.

Numerous mechanisms have been proposed for the uptake of ions. They are no different for the radionuclides in fallout than for general uptake processes in plants, except that all reactions are in the low concentration realm. Most mechanisms postulate the participation of a carrier compound or process. Some ions, e.g., calcium, strontium, and barium, seem to compete for an identical carrier, whereas others, e.g., potassium, rubidium, and cesium, compete for a different carrier (NAS-NRC 1957, p. 9). Translocation within the plant was greater for cesium, rubidium, and potassium than for strontium, calcium, yttrium, and other multivalent cations.

An interesting mechanism that can by-pass the soil reactions is absorption from the so-called plant base. This is the mat of roots, basal portions of stems, and organic matter on the surface of the soil. Experiments showed that absorption from this could be fairly large and that the process might account for some anomalously high strontium concentrations in pasture vegetation (NAS-NRC 1957, p. 11).

For more recent research with plant uptake, we turn to a short glimpse of the large and growing literature with the actinides. Much of the work was done at the same institutions we have been quoting, but there were also newcomers such as LLL, Colorado State, and others. A very useful compendium is the volume already quoted in other connections: *Transuranic Elements in the Environment*, edited by Wayne C. Hanson at Battelle, Pacific Northwest Laboratories (Hanson 1980). The synthesis of the research literature by many of the principal workers in the field (Watters et al. 1980) presents the results of many experiments on plant uptake and distribution in plants of the transuranics. Neptunium in valence V state was taken up to a much greater extent than plutonium, valence IV; americium, valence III; or curium, valence III. The relative uptakes were plutonium = 4, americium = 35, curium = 39, and neptunium = 3×10^4 . When solubilized to valence VI, plutonium was more readily absorbed, but it appears to revert to the IV state within the plant tissues and become less mobile again. Concentration ratios^(a) varied not only between plants and among elements, but they were different in experimental studies compared to field studies. In experimental studies, the concentration ratios for plutonium isotopes were 10^{-5} to 10^{-4} for native plants, 10^{-10} to 10^{-3} for agricultural crops; for ^{241}Am from 10^{-5} to 10^{-2} and 10^{-7} to 10^{-1} , respectively; 10^{-4} to 10^{-1} for ^{244}Cm ; and 10^{-2} to 10^{-1} for ^{237}Np in native plants.^(b) In field studies, the ratios tended to be about a factor of ten lower (Watters et al. 1980).

Does this result mean that some sort of solubilizing processes occur in the field? Yes. Such processes have been found by comparing sterile and microbially active soils in the laboratory. Wildung and Garland (1980) present evidence for microbial alteration of the solubility of plutonium in soil and enhancement of the uptake by plants. Changes in solubility with time and number of crops were described from Pacific Northwest Laboratory somewhat earlier (Vaughan 1974) but not specifically tied to microbial action. The answer seems to be that some of the relatively insoluble radionuclides may become more soluble with time, cropping, cultivation, etc.

(a) Transuranic concentration in receptor/transuranic concentration in donor.

(b) Agricultural crops appear not to have been studied in much detail with the latter three actinides. The ranges for these are so large that the apparent differences may be spurious. However, the investigators, with the full data at hand, concluded that there was a difference.

The transuranics were distributed more nearly uniformly in various plant parts than the fission products but with large differences among the elements. The seed persisted in having very little plutonium, americium, or curium, just as occurred with the fission products. However, there was considerably more ^{237}Np in seeds. A summary of these phenomena, taken from the review by Schreckhise and Cline (1980), is given as figure 13.18.

FIGURE 13.18. Uptake and distribution of plutonium, americium, curium, and neptunium. (Redrawn from Schreckhise and Cline 1980.)

We will close this section on plant uptake and distribution of the transuranics by listing the titles for most of the remaining papers from the special issue of *Soil Science* cited earlier. The University of California, Los Angeles, was a prime contributor to this work.

"Plant Uptake of ^{237}Np , $^{239,240}\text{Pu}$, ^{241}Am and ^{244}Cm from Soils Representing Major Food Production Areas of the United States." E. M. Romney, A. Wallace, R. K. Schulz, J. Kinnear, and R. A. Wood.

"Relationship between the Chemical Extractability of Several Transuranic Elements from Soils and Their Uptake by Wheat Plants." H. Nishita, A. Wallace, E. M. Romney, and J. Kinnear.

"Relative Adsorption and Plant Uptake of ^{238}Pu and ^{239}Pu in Soils." H. Nishita.

"Uptake and Translocation of Neptunium-237, Plutonium-238, Plutonium-239, 240, Americium-241, and Curium-244 by a Wheat Crop." R. K. Schulz and M. R. Ruggieri.

"Plutonium, Curium, and Other Radionuclide Uptake by the Rice Plant from a Naturally Weathered, Contaminated Soil." D. C. Adriano, K. W. McLeod, and T. G. Ciravolo.

"Uptake of Plutonium from Soils Contaminated by a Nuclear Fuel Chemical Separations Facility." K. W. McLeod, D. C. Adriano, and T. G. Ciravolo.

"Studies on Unsaturated Zone Hydrology and Radionuclide Migration at a Shallow-Land Burial Site." R. K. Schulz, E. B. Fowler, E. H. Essington, and W. L. Polzer.

"Effect of DTPA on Concentration Ratios of ^{237}Np and ^{244}Cm in Vegetative Parts of Bush Bean and Barley." E. M. Romney, A. Wallace, R. T. Mueller, J. W. Cha, and R. A. Wood.

"Effect of Concentration on ^{241}Am Uptake by Plants with and without DTPA Treatment." A. Wallace, E. M. Romney, R. T. Mueller, Sr., and S. M. Soufi.

"Plant Uptake and Transport of ^{241}Am ." A. Wallace, E. M. Romney, R. T. Mueller, Sr., and S. M. Soufi.

"Effect of Various Concentrations of DTPA Chelating Agent in Soil on Uptake and Distribution of ^{241}Am in Bush Bean Plants." A. Wallace, E. M. Romney, and R. T. Mueller.

"Frequency Distribution of ^{241}Am in a Population of Bush Bean Plants Grown in Soil in a Glasshouse." J. E. Kinnear, A. Wallace, and E. M. Romney.

Obviously, much of this later research bears on waste disposal problems, but it grew out of the problems of fallout and began with the problems of radioisotopes in the environment of the early atomic energy sites and thus is quite general in its applicability.

c. Foliar Absorption and Distribution Therefrom

It has been known since the 1930s that many substances in liquid or even solid form, in addition to gases, could be absorbed through plant leaves. This fact made interpretation of some of the fallout phenomena seen in the field tests easier, e.g., the phenomenon of plants with considerably higher contents of radionuclides than those measured in the surrounding soil. While some interpretations could be made by analyses on the test sites, more reliable information, particularly information pertinent to mechanisms, could be obtained under greenhouse conditions. Such work was done at nearly every laboratory having such facilities and an interest in plant uptake of fallout radionuclides. Frequently, the procedure was simply to apply an aerosol and then measure uptake and translocation. In other instances, variables were introduced that might bear on interpretation of mechanisms.

The NAS-NRC report of 1963 quotes UCLA work showing that most of the fission-product radioactivity associated with vegetation near NTS was in external dust and that mechanical trapping by hairs, glands, and stomata played an important role. Particles of less than $44\text{-}\mu\text{m}$ diameter were retained preferentially, while larger sizes were poorly retained (a general finding for other aspects of the NTS phenomenology—see chapter 12). Autoradiograms showed that strontium can enter directly through the intact epidermis of tomatoes (Martin 1954).^(a)

There were large species differences, dependent it would appear, on the degree of waxiness of the leaves. Retention and absorption by wheat plants was high (93% of applied cesium and 85% of applied strontium), while cabbage leaves absorbed only a few percent of the applied radioactivity. As a corollary, it was found easy to wash foliar depositions from some plants, almost impossible from others. These differed for different elements and, of course, the compound applied.

(a) This is not a universal finding for fruit.

The time in the growth cycle seemed to make a difference too. Absorption from foliar deposition was more rapid and larger if it occurred during periods of rapid growth. This implies a link of the processes, in part at least, to metabolic functions and is a general finding.

Biddulph (1960), from Washington State University, presented a reasonably complete review of foliar entry and distribution of fallout radionuclides and the mechanisms thereof at the Minnesota symposium cited many times. The processes are complex because leaf surfaces are complex. Briefly, there are two important phases: (1) exchangeable binding of ions to negatively charged biocolloids or to nondiffusible anions in the cell wall, and (2) active uptake into protoplasmic constituents of the cells. Specific ion-binding substances are postulated to take part in this process. If the element has no ionic partner, as is the case with many of the heavier fission products, it will not be taken into the cells and thus will remain in the axils of the leaves more or less indefinitely. Translocation of materials once absorbed is also quite variable among radionuclides. Some elements, such as divalent strontium, are largely immobilized within the leaf and accumulate in those leaves into which they are absorbed. Cesium, like potassium, is largely transported elsewhere after entering the leaf.

In the same volume, Middleton (1960), from the United Kingdom, details the very large contribution that foliar absorption can make and examines the influence of conditions but does not dwell much on mechanisms.

Investigators in the Department of Horticulture at Michigan State University became interested in the mechanisms of absorption of fission products by above-ground plant parts and presented a nice summary in the Fowler book (Bukovac, Wittwer, and Tukey 1965). They point to many similarities of the mechanisms of foliar absorption to those of root absorption. However, they are far from identical. This is illustrated by the relative rank of several fission products for foliar and root absorption and for redistribution, as shown in table 13.16.

TABLE 13.16. Classification of Certain Selected Fission Products as to Ease of Absorption by Foliage and Roots, and Redistribution Subsequent to Absorption

Process	Relative rank			
Foliar absorption	$^{137}\text{Cs} >$	$^{140}\text{Ba} >$	$^{89-90}\text{Sr} >$	^{103}Ru
Root absorption (soil)*	$^{89-90}\text{Sr} >$	$^{140}\text{Ba} >$	$^{137}\text{Cs} \approx$	^{106}Ru
Redistribution**	$^{137}\text{Cs} >>>$	$^{89-90}\text{Sr} >$	$^{140}\text{Ba} >$	^{103}Ru

*Data adapted from Nitschita et al.

** ^{137}Cs is readily redistributed from one plant organ to another, whereas, the others are not.

It is notable again that cesium is easily redistributed after foliar absorption, whereas strontium is quite immobile. The authors list several other ways in which foliar and root absorption differ^(a) and the many factors that may influence absorption by above-ground plant parts.

(a) In this as in many of the other research programs, distribution within the plant was demonstrated by autoradiography as well as by radiochemical analysis.

A full session was devoted to foliar absorption work at the Stockholm symposium on radioecological concentration processes (Åberg and Hungate 1967). Much of the work was from European laboratories. Kirchmann, Fagniant, and Van Puymbroeck (1967)^(a) from Mol, Belgium, used a motor sprayer to place artificial airborne contamination of radiostrontium or radiocesium on rye grass and red clover grown in pots. Their object was description of the influence of various factors on foliar retention. Radionuclide concentration had relatively little effect on the percentage retained. There was a small effect of the amounts of stable strontium or cesium on the $^{137}\text{Cs}/^{89}\text{Sr}$ ratio. The relation to plant yield seemed to be largely determined by geometry of the shoot or the nature of the cuticle. Moisture increased foliar retention in clover but reduced it in rye grass. Light intensity, surprisingly, had little effect, but temperature made considerable difference with uptake. It was greatly reduced by lowered temperature, and translocation essentially stopped below 21°C.

Merten and Buchheim (1967) from Kiel, West Germany, studied the influence of the microstructure of the plant surface on "fixation" of radiostrontium. The plants were dipped into solutions for periods from ten seconds to ten minutes and subsequent retention measured. Surfaces that were hydrophobic showed uptake capacities an order of magnitude lower than hydrophilic surfaces. In other work from Germany (Frankfurt), factors such as structure and arrangement of leaves and the density of standing growth were investigated (Nay 1967). The sparser the standing growth, the greater the contamination in a given plant. This seemed to have as much effect as species and structure.

Of considerable interest is work reported by C. F. Miller from the Stanford Research Institute in Menlo Park, California, on retention by foliage of silicate particles ejected by a volcano in Costa Rica (Miller 1967). Since much of the radioactivity deposited from fallout is in relatively insoluble form, such as silicates, this work is pertinent. It was largely observational. There was a large difference in contamination factors between this situation and foliar contamination in the weapons tests. Retention factors were as much as one-thousand times larger for the volcanic materials. It is suggested that the material from weapons tests had been subjected to more weathering. Retention under damp conditions was about twice that under dry conditions. The size distributions on the plants were about the same as in the ground, again in contrast to the classic 44- μm rule developed by UCLA (chapter 12) for NTS. It was again explained by longer weathering in the latter case.^(b) Menzel (1967) provided a different view of airborne nuclides and plants. This work took cognizance of the mechanisms of airborne transfer with and without rainfall (chapter 15), and it includes naturally occurring radionuclides such as radon and daughter products.

At an IAEA symposium in Vienna, the Oak Ridge group provided a very specific experiment with artificial fallout and a very specific crop, fescue. The abstract of this paper by Dahlman, Auerbach, and Dunaway (1969) gives some details:

(a) Another review of the same period was presented at a symposium of the AAAS, Agriculture and the Quality of Our Environment (Menzel 1967).

(b) The people at PNL interested in aerosols seized an opportunity to study fresh volcanic ash from the Mt. St. Helens eruption in 1980. Sanders, Gelman, and Conklin (1981) measured pulmonary retention and toxicity and concluded that the volcanic ash was essentially inert physiologically.

BEHAVIOUR OF ^{137}Cs -TAGGED PARTICLES ON A FESCUE MEADOW. Enclosures of tall fescue (*Festuca arundinacea*), 0.01 ha in area, were contaminated at the rate of 25 g/ft² using artificial fall-out (^{137}Cs fused to 88-177 μm silica sand, $\sim 100 \mu\text{Ci/g}$, 15% leachable in water) to study the effects of close-in fall-out on a grass system. Investigations of radiation effects, intercompartmental cycling of radiocaesium and secondary movements of the simulant particles in soil and litter have been in progress since mid-summer, 1968. Plant community response (yield, seed production and species composition), small mammal physiology (haemopoietic and gut effects) and insect population dynamics are being studied following exposure to chronic internal-external, beta-gamma radiation. Sand particles intercepted by grass blades were readily dislodged by light wind, and maximum retention time was approximately 10 days. The simulant was readily trapped in the leaf axils where it remained for 4 weeks until washed off by rain. There was significant transfer (15%) of ^{137}Cs from simulant to vegetation. Vacuum and brush cleaned vegetation initially contained 1.32 $\mu\text{Ci/g}$ (living parts) and 4.62 $\mu\text{Ci/g}$ (dead parts).

Early incorporation into foliage was largely by contact assimilation because appreciable uptake had occurred before the simulant had reached the soil. Two loss rates were evident in the subsequent decrease of ^{137}Cs in living foliage. The fast component, which began 8 days after contamination and continued for 4 weeks, was described by the linear regression $Y = 1.64 - 0.04X$ where Y and X are $\mu\text{Ci } ^{137}\text{Cs/g}$ foliage and days, respectively. The slower loss rate commenced 4 weeks after contamination and its regression was $Y = 0.61 - 0.003X$.

Only 0.12 mCi of ^{137}Cs (0.006 % of that present) was carried from the tagged areas in one runoff event. This agreed remarkably well with that predicted from a simple model based on characteristics of simulant and soil, and on rainfall-runoff relationships. (Dahlman, Auerbach, and Dunaway 1969)

While not particularly mechanistic, this experiment provides a good example of the relatively clean-cut information that carefully planned and executed field research can provide.

More work from abroad appeared in this symposium. The review by Keppel from the Federal Republic of Germany (Keppel 1969) gives a good comparison of the factors in roots and leaves that favor or inhibit absorption and makes it clear that these sometimes reinforce each other and sometimes work in opposite directions.

As expected, considerable research was done on the interaction of plutonium and other relatively insoluble actinides and plant foliage. This includes the role played by wind resuspension, details of which will be reserved for chapters 14 and 15.

A useful review of the general phenomena has been presented by Cataldo and Vaughan from PNL in the volume by Hanson quoted earlier (Cataldo and Vaughan 1980).^(a) The work shows that submicronic particle sizes are more effectively retained on plant foliage than are larger particles, that submicronic particles become less available for leaching with increasing residence time on the leaf, and that up to 90% of foliar plutonium deposits may be firmly held. A diagram of the glove box and miniature wind tunnel used for these Battelle studies (Klepper and Craig 1974) is shown as figure 13.19. The wind velocities in this experiment were very low.

(a) This followed earlier reports by Klepper and Craig in 1974 and a paper by Cataldo, Klepper, and Craig (1976), the latter giving considerable experimental information.

FIGURE 13.19. Transverse section of glove box and aerosol exposure wind tunnel. (Redrawn from Klepper and Craig 1974.)

Finally, lest we forget that plant leaves are freely permeable to gases such as oxygen and CO_2 , we should remark that a fairly considerable amount of work was done, much of it at the Savannah River Plant of AEC on tritium and tritiated water vapor. An example is research by Murphy and Corey (1976) in which branches of pine trees were enclosed in clear plastic bags containing tritiated water vapor. The conditions were such that all absorption would take place from the vapor phase. It was concluded that tritiated water vapor diffuses into foliage (of pine trees, at least) by the same pathway as water vapor diffuses out. It can be expected that tritium water vapor will be rapidly and completely exchanged in all plants.

The research on foliar absorption seems to have resulted in information more pertinent to botanical mechanisms than to the problems of fallout per se, except to prove in laboratory environments that foliar absorption of radionuclides can be very significant and that it is far from a simple process.

d. Effects on Plants

We discussed effects of radiation and radionuclides in ecosystems as part of chapter 11, and effects on animals have appeared in nearly every chapter. We saw in chapter 12 that descriptions have been given of the effects of fallout and also direct radiation on plants and plant communities on the Pacific atolls and at NTS. We also alluded earlier to the large experiments on plants with external radiation sources done at Brookhaven, Oak Ridge, Emory University, and elsewhere.

Radiation botany became a very active research area. Brookhaven was a mecca for this work, particularly because of the presence of Arnold Sparrow, George Woodwell, and many colleagues. It became the home base for a

journal, *Radiation Botany*, of which Sparrow was editor-in-chief for many years.^(a) Essentially all of the work utilized external sources of radiation.

At the unicellular and embryonic stages, plant and animal tissues have been found to react more or less similarly to radiation. At the more mature stages, higher plants show large differences from animal tissues. An excellent general summary of the type of work, the problems, and the findings can be seen in the chapter on plants in the text by A. P. Casarett (1968) already cited.

Work with the large field installations at Brookhaven and elsewhere showed that pine trees were relatively more sensitive than other trees. The doses to produce effects in higher plants were generally rather high, however. For this reason, very few attempts were made to do experimental effects research with radionuclides incorporated into plants. The potential contamination problems associated with such work were a strong deterrent.

The NAS-NRC report quotes some Russian work on metabolic effects from incorporated ^{90}Sr and ^{137}Cs and reduction of grain yield in wheat. The concentrations needed were 5 μCi of ^{90}Sr or 13 μCi of ^{137}Cs per gram of wheat. Resistance to radiation increased as the plants grew older. There was also some work with ^{32}P in young barley plants. The lowest-specific-activity level at which damage occurred was 170 μCi of ^{32}P per gram dry weight, and this damage was confined to the zones of active division (NAS-NRC 1957, p. 14, quoting work by Blume, Hagan, and Mackie 1950).

On the assumption that the effects of external radiation on plants apply in a general way to equivalent doses from deposited radionuclides, we can draw a few conclusions as to what effects research with these might show had it been done on a larger scale.^(b)

Three tables taken from the chapter by Casarett (1968) on the effects of radiation on higher plants and plant communities show the levels of dose associated with effects in plant communities and the predicted exposures required to produce from slight effects to LD_{100} (one hundred per cent kill) for a variety of plant species and communities.^(c) These are gathered together as table 13.17A, B, and C.

Remember that these data are all based on external radiation and that doses are expressed in roentgens (R). They confirm, as do data for individual plants and plant parts presented earlier in the same work, that higher plants are, in general, less radiosensitive than terrestrial animals. Since concentration factors for radionuclides in plants are not high, in general, these relationships can be expected to hold approximately also for the radionuclides from fallout.^(d)

It will be noted that table 13.17A and C contain information on chromosome volumes and number. This ties to what may be some of the most intriguing research on radiation effects in plants. This came from Brookhaven and work by Arnold Sparrow and his associates, especially George Woodwell. They made a systematic study of the doses required to produce growth inhibition under chronic exposure conditions, in a large number of plant species. There was an

(a) The journal operated from 1961 until December 1975 when it became *Environmental and Experimental Botany*, partly because of the untimely death of Dr. Sparrow.

(b) Much work was done with incorporated tritium as discussed in earlier chapters.

(c) A series of pertinent earlier papers is gathered in the First National Symposium on Radioecology.

(d) With the usual greater sensitivity of embryonic and growing tissues seen in all life forms.

TABLE 13.17A. Estimated Acute Exposures Required to Affect Dominants in the North American, Eastern Deciduous Hemlock-Hardwood Forest

Species	Somatic chromosome number	Interphase chromosome volume ($\mu^3 \pm \text{S.E.}$)	Sensitivity range: slight inhibition of growth to mortality (R)
<i>Tsuga canadensis</i> (hemlock)	24	21.3 ± 0.8	420-1,100
<i>Betula lutea</i> (yellow birch)	84	2.2 ± 0.1	3,860-10,120
<i>Pinus strobus</i> (white pine)	24	46.5 ± 2.8	190-500
<i>Pinus resinosa</i> (red pine)	24	43.2 ± 3.5	210-540
<i>Acer saccharum</i> (sugar maple)	26	3.2 ± 0.2	2,800-7,360

TABLE 13.17B. Estimated Radiation Exposures (R) Required to Damage Major Natural Communities

Communities	Level of damage		
	Minor	Intermediate	Severe
Coniferous forest	200	200-2,000	> 2,000
Deciduous forest	200	200-10,000	>10,000
Grassland	2,000	2,000-20,000	>20,000
Herbaceous annuals	4,000	4,000-70,000	>70,000

TABLE 13.17C. Predicted LD₁₀₀ Values and Acute Exposure Required to Produce Slight Effects on Vegetative Growth of Vegetable and Field Crops

Species	Estimated interphase chromosome volume ($\mu^3 \pm \text{S.E.}$)	Predicted exposures required to produce	
		slight effects (R)	LD ₁₀₀ (R)
<i>Allium cepa</i> (onion)	39.3 ± 2.3	377	1,491
<i>Triticum aestivum</i> (wheat)	14.6 ± 1.1	1,017	4,022
<i>Zea mays</i> (corn)	14.0 ± 0.6	1,061	4,197
<i>Solanum tuberosum</i> (potato)	4.6 ± 0.3	3,187	12,608
<i>Oryza sativa</i> (rice)	3.0 ± 0.1	4,974	19,677
<i>Phaseolus vulgaris</i> (kidney bean)	1.6 ± 0.1	9,137	36,149

Source: Reset from Casarett 1968, who had modified them from Woodwell and Sparrow 1965 for A and B and Sparrow et al. 1965 for C. Reprinted with permission of Prentice-Hall, Inc. Englewood Cliffs, New Jersey, copyright 1968, 1965.

excellent correlation between the average interphase nuclear volume and the daily dose required to produce severe growth inhibition. They covered twenty-three species of diploid cells with average nuclear volumes from 23 to 1,000 μ^3 , i.e., a factor of about fiftyfold. Another measure of the volume of nuclear material is ploidy. The higher plants show much more tendency to have cells with multiple ploidy than do animal cells. Sensitivity could be correlated with ploidy with greater sensitivity in the diploid state and less sensitivity as ploidy increased. Both of these phenomena are illustrated in figure 13.20A and B, taken from Sparrow and Woodwell (1963).

FIGURE 13.20A. Relationship between nuclear volume and daily dose rate required to produce severe growth inhibition in twenty-three species of plants chronically irradiated. (Redrawn from Sparrow and Miksche 1961. Reprinted with permission of Science, Washington, D.C., copyright 1961.)

FIGURE 13.20B. Relationship between radiosensitivity and degree of polyploidy in 175 species of chronically irradiated plants. "X" in the legend refers to the ploidy of the group. (Redrawn from Sparrow and Evans 1961.)

On the basis of such correlations, Sparrow and Woodwell (1963) and Sparrow and Miksche (1961) were able to predict radiosensitivity of a large variety of higher plants.^(a) There is no reason to expect that the same general relationships would not hold for sensitivity to incorporated radionuclides.

Nevertheless, we must base our conclusions on the data at hand and derive ideas for effects of radionuclides by extrapolation from research with external radiation sources. The subject is still lively. A two-volume series edited by L'Annunziata and Legg (1984) considers many aspects of isotopes and radiation in agriculture. Evidently there are more volumes planned.

IV. Selected Radionuclides

This section is intended to highlight some of the results of the extensive research on the radionuclides present in fallout, with particular emphasis on those that have received the most attention, and thus can be considered as entities. We will emphasize that work most obviously associated with the problems of fallout per se, but for comparative purposes will include some work begun under the conditions described in chapter 8 before the fallout problems became of consuming interest. References will perforce be sparse except for summaries and some previously unreferenced documents. The bearing of the research findings on the possibility of *health effects from environmental exposures* will occupy our attention now.

A. Strontium

Of all the fission products, isotopes of strontium have received the most research attention by far. In addition to the general summaries already cited in this chapter (*Radioisotopes in the Biosphere*, 1960; *Radioactive Fallout, Soils, Plants, Foods, Man*, 1965; *Strontium Metabolism*, 1967; *Radioecological Concentration Processes*, 1967; *Biomedical Implications of Radiostrontium Exposures*, 1972; United Nations Scientific Committee 1977 and 1982, and the several national symposia on radioecology),^(b) the reader may also wish to consult the strontium reports for the Federal Radiation Council (FRC) (chapters 12 and 16), the BEAR reports (chapter 12), the several Hanford and Utah symposia discussed at length in chapter 8, and a small but succinct book edited by Engstrom et al. (1957). A relatively unknown but important summary concentrating on the pediatric significance of peacetime radioactive fallout was sponsored by the American Academy of Pediatrics (Pediatrics 1968). It provides a broad summary, despite its orientation toward pediatrics. It does not emphasize experimental work but includes some.

(a) This discussion should not be taken as the whole story. There are many factors, environmental and intrinsic, that can modify the response as compared to the standardized laboratory experiment performed at Brookhaven. Also, some of the unicellular plants (e.g., yeasts) do not fit the pattern very well. Further discussion is beyond our scope here.

(b) See chapter 11.

1. Generalizations from the Large-Animal Experiments with Strontium

It is now clear that the ^{90}Sr - ^{90}Y couplet has become a bench mark or reference system for all consideration of bone-seeking beta emitters, much as ^{226}Ra became the bench mark for bone-seeking alpha emitters. The couplet has been studied in a number of different species over very long periods utilizing several different routes of administration.^(a) The large experiments are now essentially complete, and a few generalizations can be made.

- a. There is an important and as yet unexplained qualitative difference between the distribution and effects appearing after oral administration and those after inhalation and most forms of parenteral administration, e.g., intravenous injection. Soft tissue effects, such as hematopoietic dysplasias and myeloproliferative disorders in general, and soft-tissue malignancies in general are much more prevalent after oral administration. Thus, the Hanford experiment with swine and the Davis experiment with dogs show qualitatively different results from the Utah and other experiments where the radionuclide was given by intravenous injection. They were different, too, from the results of inhalation exposure done at Lovelace (Inhalation Toxicology Research Institute). It is true that bone tumors could be produced on all dosage regimens, and some soft-tissue effects could be seen at high doses in nearly all experiments. It was the mix of bone tumors and soft-tissue tumors and other effects referable to soft tissue, including bone marrow, that was so strikingly different. This contrast was first highlighted by McClellan and Jones (1969) in a masterful review prepared for one of the Utah symposia.
- b. Quantitative differences have appeared with different dosage patterns. "In general, exposures that resulted in high-initial dose rates, followed by protracted exposure of localized areas of tissue predisposed to the development of osteogenic sarcoma . . ." (McClellan and Jones 1969, p. 314). The incidence of neoplasms of the hematopoietic system did not show this relation to dosage pattern.
- c. Those experiments that covered more than one generation showed remarkably little effect of a strontium body burden on reproductive performance or on the health of the offspring. Indeed, doses required to produce easily measurable effects on farrowing or on the offspring tended to be definitely toxic to the mother, enough so that parturition was difficult. This generalization seems to have been forgotten in some of the polemics regarding long-term effects of fallout. While it can be argued that long-term studies of the offspring were not sufficient to turn up any subtle genetic or behavioral effects, the above conclusion appears to be based on voluminous and carefully executed experimental work.
- d. The work on strontium contributed enormously to our knowledge of the biochemistry and physiology of bone.

(a) The yttrium component of ^{90}Sr - ^{90}Y equilibrium mixtures is not absorbed from the gut. Therefore, in feeding experiments, the contribution of yttrium comes from that which grows in from the strontium that has been absorbed. In general, when an experiment is stated as having been done with ^{90}Sr , it was usually the ^{90}Sr - ^{90}Y mixture that was given. If injected, the preformed yttrium was included in the effective dose, but if ingested, it was not, except for its dose to the gut wall.

- e. While strontium is clearly able to produce bone tumors, they occur only at quite high levels of radiation dose. There is a very low incidence at the lower levels of radiation dose, even though such levels are well above those associated with fallout from the nuclear weapons tests or normal peacetime operations of the nuclear enterprise. It is very unlikely that the few remaining animals in the large experiments will change this conclusion.^(a) Thus, it is the catastrophic event that poses a real threat from intake of radiostrontium insofar as cancer is concerned.^(b)
- f. Genetic effects of strontium did not receive generous attention, despite the allegations of Sternglass (see chapter 12). The gonadal dose is very small, and in larger animals and man, the gonads are far enough from surrounding bone not to receive a large dose in this manner. The few experimental studies indicate that somatic effects will far outweigh genetic effects of strontium in higher mammals.
- g. The data from the long-term animal experiments have provided the basis for the only complete and tested model for radionuclides in bone, the so-called Marshall model. This used the Norris power function relationship for retention of strontium (see chapters 7 and 8, also Norris and Kisielski 1948) for extrapolation to man. However, there were complications. A large difference in retention time between compact and cancellous bone was apparent. Many preferred a series of exponential functions over the power function as being more physiological and susceptible to future compartmental analysis. The alkaline-earth model as it appears in ICRP Publication 20 (ICRP 1973) recognizes the differences between bone types, but still uses power functions, albeit modified by an exponential. The data are still being reviewed.
- h. The several authors reporting on the long-term experiments concluded that the dose-response relationships were unlikely to be linear to dose.

Tables illustrating the effects of ^{90}Sr (^{90}Y) in the several large animal experiments are given below.^(c) In table 13.18, the bone sarcoma incidence in the Utah dogs as of 1987 is given as part A; bone sarcoma, myeloproliferative disorders, and malignant tumors of soft tissues in the dogs at Davis as part B;^(d) the bone sarcoma, hematopoietic dyscrasias, and soft-tissue tumors in the dogs receiving ^{90}Sr by inhalation at Lovelace as part C.

- (a) A new bone tumor has been found on histological examination of bone from a long-dead Utah dog (Lloyd, personal communication 1987). Thus, the story is not yet complete.
- (b) The long-lived bone-seeking alpha emitters do not show this phenomenon to such a marked degree; the dose-response is more gradual. Effects on other systems were less regularly related to dose.
- (c) Information in this section was extracted from recent tabulations drawn together by a Task Group of the NCRP, chaired by R. D. Lloyd, University of Utah. Contributing members were, P. Durbin, Berkeley; R. Jones, Lovelace; N. J. Parks and R. Pool, Davis; and H. Ragan, PNL. They are brought together here with permission of Dr. Lloyd and with the understanding that they are subject to revision and may or may not represent a consensus of all concerned. The final report is still in preparation. An update to 1987 was supplied by Dr. Lloyd in December 1987.
- (d) The NCRP report will also show results with ^{226}Ra at Davis.

TABLE 13.18. Summary of Dog Experiments with Radiostrontium**A.** Utah—Injection. Bone Sarcoma as of 1987.

Inj. $\mu\text{Ci/kg}$	Avg. yr inj. to death	No. of dogs	Sar.(a) dogs	Incidence (%)	Avg. Skel. rads at death
97.9	3.40	14	8	57.1	10,714

A general survey of the most commonly observed effects in the three-generation experiment on swine at Hanford is given as table 13.19A and the neoplasia incidence in female swine ingesting ^{90}Sr in table 13.19B. The contrast between ingestion and other routes is highlighted by these summaries.

The results of the work with cats done by the PHS (see section I.F) are not included in tables 13.18 or 13.19 because they were not analyzed by the NCRP group cited above. It was a fairly large program, but perhaps because the project was moved from Cincinnati to Rockville in midstream, so to speak, and because the shorter half-life isotopes of strontium were used, it could not be as long-term as the dog and swine experiments, and it has not received the same continuity of reporting or comprehensive reviews. This work constitutes the only extensive U.S. study of the effects of the shorter half-life strontium isotopes in a species with relatively long life span. The rest of the work with shorter half-life strontium isotopes was done with rodents. The work with cats follows.

Annual reports (DHEW 1966, and sequels) describe the experiment and present results for both metabolism and effects. Two summary reports in 1972 give an overview of the findings (Ward and Wright 1972; Ward et al. 1972). This was well after the EPA had taken over the Twinbrook Laboratory from the PHS.

TABLE 13.19A. Summary of ^{90}Sr Dose Effects in Miniature Swine, Work at Hanford

$\mu\text{Ci/day}$	Observed Effects	Mean Survival Time
625	Pancytopenia-Hemorrhagic crisis, Myeloid Metaplasia	3 months
125	Pancytopenia-Hematopoietic neoplasia, Bone Tumors	3.5 years
25	Neutropenia-Neoplasia	10 years
5	Neutropenia	11 years
1	Neutropenia	11 years

(a) Two removed from ^{90}Sr feeding at 3 months of age developed bone tumors and leukemia at 3 and 4 years of ages; remaining animals not removed from ^{90}Sr died at about 3 months of age from bone marrow aplasia.

(b) Two of these tumors were malignant.

(c) All ovarian tumors were malignant.

(d) Four of these tumors were malignant.

(e) Seven of these tumors were malignant.

(f) Four of these tumors were malignant.

(g) Six of these tumors were malignant.

Source: See footnote c, p. 1149.

The route of administration was oral, the feeding period thirty days. Thirty-three cats were involved in the final reports. Bone marrow lesions were extensive and dose-related, and there was hemorrhagic disease with many hemorrhages observed in various organs. At the cellular level, bone marrow cells showed degenerative changes. Neoplasms of both bone and soft tissues adjacent to bone did occur at longer periods (incidence: four lesions in three cats). Thus, this work was consistent with the findings with ^{90}Sr , viz., the oral route shows relatively more soft tissue damage than intravenous or inhalation routes of intake.

As already mentioned, the work with monkeys at Berkeley was very useful for metabolism data, but the doses were not high enough to produce clear-cut biological effects.

These data with large animals tie closely in concept and conclusions to the large experiments with mice described in chapter 8 and also briefly in section II of this chapter.

2. Experimental Work on Man with Strontium

We have already mentioned that work was done with radiostrontium in man by Dr. Herta Spencer and colleagues at the Hines Veterans Administration and the

Montefiore Hospital in New York. This was collaborated on by investigators at HASL and Brookhaven. (See, for example, Spencer, Laszlo, and Brothers 1957; Spencer et al. 1958; Laszlo and Spencer 1959; Spencer et al. 1967, 1972; Spencer, Kramer, and Samachson 1972; and references cited in chapter 19 concerning chelation therapy.) All of this research indicated behavior in man comparable to that found in the animal experiments.

Probably one of the least known semiexperimental studies with radiostrontium in human beings in the United States was done under the auspices of the U.S. Department of Health, Education and Welfare, Bureau of Radiological Health (Kahn et al. 1969). It was a four-year program with infants done largely in the Cincinnati, Ohio, area. It was a metabolic balance study of healthy infants using consecutive twenty-eight-day balance periods. No strontium was given experimentally. There was sufficient radioactivity from fallout, particularly strontium isotopes, to permit reasonably accurate determinations of intake and output and thus metabolism. Metabolic models were designed for calcium and strontium in the infant. They measured stable as well as radiostrontium balance; they produced a detailed picture of gross retention, observed ratios, and accumulation in the body. The data were compared to models for the very young developed from animal experiments by the people at Utah and elsewhere.

Much work on whole-body retention of the alkaline-earths in man was done abroad and has been cited in part elsewhere.

In chapter 6, we mentioned Hamilton's early idea that radiostrontium might become a therapeutic tool. Little was done on effects in man after that work was discontinued. The only study that looked seriously for effects in man came not from an interest in fallout but from work with luminizers in Czechoslovakia, which was described briefly in chapter 1. Müller and colleagues (1961) measured urinary excretion of strontium-yttrium in many workers and found signs of hematological changes. This was followed up by a large study described in a monograph from the Institute of Radiation Hygiene in Prague (Müller and coworkers 1970). The body burdens estimated from urinary excretion were confirmed by whole-body counting. Karyological examinations of circulating peripheral lymphocytes were considered worthy of consideration as a biological dosimeter, but no clearly deleterious effects were found.

B. Iodine

There were no extensive animal experiments with radioiodine generated by the problems of fallout that we have not already reviewed at least in part. The Hanford symposium on iodine, held in 1963 and discussed in some detail in chapter 8, was exceptionally complete, partly because the work got an early start around the site-specific problems. The really new information has come from the environment itself and clinical medicine.

It was around iodine that the importance of the food chain was highlighted, particularly the role of the contamination of milk, which led to drastic reduction of permissible releases, as we have seen. Also, the environmental work led to de-emphasis of the importance of the inhalation pathway for iodine. The chief contributions of experimental research to these matters were to confirm and strengthen, under controlled conditions, the conclusions already reached on the basis of environmental investigations.

The above is not to imply that experimental work with iodine came to a standstill. It did not, but its orientation was more general than fallout problems

alone. One of the key questions through many years of new experimental work is one that has as much bearing on nuclear medicine and clinical aspects of iodine as on fallout problems. This is the question as to whether or not the different isotopes of iodine, with their very different half-lives and thus different specific activities, have different degrees of effectiveness. Also, are they different from a comparable absorbed dose of external radiation? Evidence began to accumulate that there was a difference. The longer-lived iodines like ^{131}I seemed to be less effective than comparable absorbed doses from external radiation or short-lived iodines. This came largely from animal experiments and clinical observations. It stimulated more experiments.

A tabular summary of much of the pertinent experimental work is shown as table 13.20, which was modified from the work of another task group of the NCRP, whose report has recently been published (NCRP Report No. 80 [NCRP 1985]). The group was chaired by Dr. Harry Maxon, University of Cincinnati. Members are S. R. Thomas and C. R. Bunker, University of Cincinnati; D. V. Becker, New York Hospital; S. A. Book, University of California at Davis; and E. L. Saenger, University of Cincinnati as advisor.

TABLE 13.20. Summary of Experimental Animal Studies on the Effectiveness of ^{131}I Relative to X-Irradiation or to Short-Lived Radioiodines

Author (date)	Species	Effect	Dose or Dosage			Effectiveness of I-131(a)
			X-ray	I-131	Other	
Tumorigenesis						
Doniach (1957)	Rat	Thyroid adenomas, cancers	1,100 rads	30 μCi , est. by Doniach to give 2,000- 24,000 rads		1/2-1/20

(a) Relative to X-ray or other radioiodine isotopes.

Source: Modified from NCRP report 1985. The cited references have been placed in the bibliography for this chapter. NCRP Task Group chaired by H. Maxon.

Obviously, there appear to be differences in effectiveness between ^{131}I and external radiation or shorter half-life iodines, with ^{131}I frequently but not always less effective. The range of differences is quite large, and decisions regarding a single figure to use for radiation protection purposes are difficult. The same type of difference has appeared in clinical studies. Saenger et al. (1963) reviewed these as early as the Hanford symposium on iodine; they have been confirmed qualitatively ever since.

This phenomenon came to light because important clinical problems stimulated investigation. Other instances where different isotopes of important

elements have different effectiveness are discussed at various points in this book, (e.g., ^{238}Pu versus ^{239}Pu).

However, there has not been a systematic investigation of the presence or causation of these phenomena throughout the internal emitter field. Thus, for estimates of risk, we frequently can only assume that a given absorbed dose from an internally deposited radionuclide will be roughly equivalent to the same dose from an external source. This may or may not be a safe generalization and is a fitting subject for future research.

As for mechanisms, in the case of iodine, dose rate and relative binding to colloid in the thyroid have been considered. In the case of ^{238}Pu versus ^{239}Pu , relative in-situ radiolysis has been considered. We need a more generalized set of explanations and investigations of the phenomena in terms of both occurrence and mechanisms.

C. Cesium

Obviously, this radionuclide received much attention in both laboratory and field. There was not as much overt organization of experimental work around it as around the bone seekers. There are few large compendia devoted to cesium compared to those for strontium, radium, plutonium, et al. We will give a very condensed overview of what was done, knowing that much of it has already been discussed.

1. Consideration of Animal Experiments

There were a few major animal experiments on ^{137}Cs . One began during the peak of research activity around fallout. This was an experiment at ANL in which about seventy dogs in three age groups were given ^{137}Cs intravenously. The doses were large: 1,650 to 4,310 $\mu\text{Ci } ^{137}\text{Cs/kg}$, and it was a lifetime study. A good review of what occurred can be found in an NCRP report on cesium prepared by its former Committee-23 on Radiation Hazards Resulting from the Release of Radionuclides into the Environment (NCRP 1977). The last animals had died just before the report was prepared, and the Argonne workers supplied the NCRP Committee with the final figures.^(a) There were also useful status reports in the ANL annual reports (e.g., Poole, Norris, and Fritz 1968).

Bone marrow destruction was a leading cause of death, but there were many other changes in soft tissue that led to fatal consequences. There was higher acute toxicity in older dogs associated probably with the increasing half-time of ^{137}Cs with age demonstrated by Tyler, Kretz, and Norris (1969). The distribution of dose was found to be clearly much more generalized than with an element like strontium. Indeed, cesium exposure is much like whole-body exposure with external radiation. In the ANL experiment, accumulated average total body dose to forty dogs surviving the acute phase was 1,170 rad (696 to 1,643 rad), with an average survival time of 3,590 days (2,010 to 5,099 days). Significant degeneration of the liver occurred in nearly all of the long-term survivors.

A somewhat later but basically similar experiment was performed at the Lovelace Foundation. There were over fifty beagles, all thirteen months of age. They

(a) The Committee was chaired by John C. Brugher until his death in 1970 and then by Walter S. Snyder. Members were Seymour Abrahamson, H. L. Andrews, C. L. Comar, G. B. Forbes, P. F. Gustafson, J. H. Marshall, C. W. Mays, and J. Rivera.

received intravenous injections of from 880 to 4,000 $\mu\text{Ci } ^{137}\text{Cs/kg}$, and the individual total body doses ranged from 550 to 2,200 rad. Bone marrow destruction was again a prominent finding, but there were many other changes, including carcinoma of various soft tissues. The total body dose required to kill 50% of the animals in this experiment was about 1,000 rad.

The total doses involved when serious effects occurred in these experiments should be compared with the much higher doses associated with bone tumors produced by strontium isotopes (tables 13.18 and 13.19). Even though some of the difference resides in the dosimetry, especially a highly localized dose versus a whole-body dose, the differences are notable. While the ^{137}Cs doses seemed high to the investigators, and indeed they are higher than the LD_{50} dose of external radiation, they are sufficiently lower than those with radiostrontium to raise questions regarding the single-minded worries about strontium in fallout and in the environment. The authors of the NCRP report are quick to point out that the effects per rad at low doses may be quite different from those observed in long-term survivors of an acute lethality experiment.^(a) This may well be true. Yet, this author views the dose from cesium associated with such marked damage as worthy of note in evaluating the long-term effects of fallout. It is true that the half-life of cesium is much shorter than that of ^{90}Sr , and it is traditional to worry most about the elements that remain in the environment for a long time, a factor that may be enough to support focusing attention on strontium. Yet, as we have gradually learned about long-term sequelae of high radiation doses given promptly, the potential for such sequelae from cesium should be earmarked for future work.^(b)

The Lovelace group included ^{137}Cs in the extensive inhalation studies described in detail in chapter 9. The soluble forms, e.g., $^{137}\text{CsCl}$, gave essentially whole-body doses and produced bone marrow aplasia by one year, as well as some neoplasia of various organs at later times. Insoluble forms, such as those in which the element is fused into aluminosilicate clay particles, were studied extensively with elements like ^{90}Sr , ^{90}Y , and ^{144}Ce but were not used much for cesium. However, there is no reason to expect that ^{137}Cs in such a form would behave very differently. In general, of course, these insoluble forms deliver large doses to lung and the respiratory tract and do not simulate a whole-body exposure. In a field exposure to fallout, it seems likely that inhalation exposures would involve a preponderance of insoluble material and thus be of less significance than soluble forms entering food chains. The bulk of the dose from ^{137}Cs in fallout could thus be via food chains, except in acute accidents. As we have already seen, cesium is very mobile in many environmental situations, especially when fresh, and it finds its way into milk and other foodstuffs with ease.

2. Experimental Work with Humans

Metabolic studies on ^{137}Cs were carried out in the metabolism ward by Herta Spencer and collaborators (Rosoff, Cohn, and Spencer 1963) much as was done for strontium. In this work, the patients had disease entities that confined them to the hospital, but their sickness was not expected to interfere with the metabolism of cesium. Tracer doses were given intravenously to four patients and

(a) No major experiment appears to have been done at really low doses of cesium, such as those that might be associated with global fallout from weapons tests.

(b) Environmental recycling of cesium adds to this concern.

orally to seven. As expected from animal experiments, the cesium was rapidly absorbed and rapidly excreted, largely via the kidneys. Nevertheless, body retention, determined from excretion data, was on the order of fifty to sixty days (retention half-time). Thus, cesium does bind to tissues and/or there is exchange and replenishment. Incidentally, there appeared to be significant binding of cesium to red blood cells (mechanism not discussed). This is reminiscent of the behavior of ^{210}Po as described in chapter 4. Tissue distribution was relatively uniform in soft tissues by ten days after intake and thereafter.

A follow-up report (Cohn et al. 1963b) described the retention of ^{137}Cs in man for extended periods using the whole-body counter at Brookhaven. The subjects were patients, two receiving intravenous doses and three receiving oral doses. Considering only the final long-term exponential component of the retention curve, values of biological half-life ranged from 54 to 114 days, with a mean of 75 days. This was within the error range of the values obtained from excretion analyses. Again they indicate that the body is not a sieve for cesium.

The experimental study by Cohn et al. lasted 343 days. A study of cesium retention in man by Richmond, Furchner, and Langham (1962), also Richmond, London, and Furchner (1964), went for 550 days in one subject and 940 days in another. (This was not experimentally administered cesium, but that accumulated from fallout.) The biological half-life was not markedly different from that in experimental studies.

These research efforts tie well qualitatively to the conclusions described earlier from site-specific and fallout data and animal experiments, including the general views found in the UNSCEAR and FRC reports.

D. Cerium

We have not placed or seen much emphasis on radiocerium per se in this book. However, it is a member of the important lanthanon series, and we have had things to say about these. The isotopes of most interest to humans are ^{141}Ce , ^{143}Ce , and ^{144}Ce . We saw much of ^{144}Ce in the inhalation experiments of the Lovelace Foundation (chapter 9) and as a component of fallout (chapter 12).

Large quantities of radiocerium are produced and released to the atmosphere in nuclear weapons testing. While not studied intensively, it has not been neglected entirely for experimental work. When a committee of the NCRP set about reviewing the findings on a number of radioelements, a very respectable volume of material on radiocerium was found to be available. It was reviewed by NCRP Committee-30, and a report was published in 1978 (NCRP 1978).^(a) The objective was examination of data particularly pertinent to radiation protection.

Concentration factors from soil to plant for ^{144}Ce are low in fish (table 11, NCRP 1978) and gastrointestinal absorption is low. However, concentration factors in aquatic foodstuffs average from one in laboratory animals (table 10, NCRP 1978) to as high as two thousand (maximum) in some mollusks. Factors against freshwater can go as high as 10,000 for some plant species. Much work

(a) The Committee was chaired by R. O. McClellan, Lovelace, and members were: J. E. Ballou, PNL; R. G. Cuddihy, Lovelace; P. W. Durbin, Berkeley; M. Goldman, Davis; M. J. (Cook) Hilyer, Oak Ridge; B. Kahn, Georgia Tech; F. W. Lengemann, Cornell; A. Lindenbaum, ANL; Y. Ng, LLL; C. R. Richmond, Oak Ridge; J. S. Robertson, Mayo Clinic; B. O. Stuart, Stauffer Chemical Company; and R. G. Thomas, Los Alamos.

has been done on the metabolism of inhaled radiocerium. Inhalation of the soluble chloride led to significant concentrations in liver and skeleton and rapid removal from the lung, whereas inhalation of an insoluble form resulted in a larger fractional dose to the lung. Several species of animals have been used (table 14, NCRP 1978). After injection, there was more ^{144}Ce in liver than in skeleton, but in small rodents it tended to leave rapidly.

Effects of cerium after inhalation have been extensively studied in the United States. An illustration of the survival and current status of beagle dogs receiving ^{144}Ce as fused aluminosilicate particles (FAP) is given as figure 13.21A. Similar information for soluble ^{144}Ce chloride is shown in figure 13.21B. Obviously, there is a different mix of effects from the inhaled soluble compared to the insoluble forms of the same element. Note also the calculated doses at which marked effects begin to occur.

FIGURE 13.21A. Dose-response relationship for the effect of ^{144}Ce on the lung and other organs of beagles after inhalation of labeled fused aluminosilicate particles (as of September 1978). (Redrawn from NCRP 1978, p. 59. Reprinted with permission of the NCRP, Bethesda, Maryland, copyright 1978.) Experimental work done at Inhalation Toxicology Research Institute.

There was some work with radiocerium using intravenous and intraperitoneal routes of administration. Some of it employed beagles, but much of it was with rodents. Much of the latter was done in the USSR. In all of these, marked damage to bone marrow, liver, and gastrointestinal tract occurred; yet, changes also appeared in lung and in skeleton, including osteosarcomas. Thus, cerium may

FIGURE 13.21B. Dose-response relationship for the effect of ^{144}Ce on the lung and other organs of beagles after inhalation of ^{144}Ce labeled chloride aerosols (as of September 1978). (Redrawn from NCRP 1978, p. 67. Reprinted with permission of the NCRP, Bethesda, Maryland, copyright 1978.) Experimental work done at Inhalation Toxicology Research Institute.

stand between the bone seekers and radionuclides like cesium that essentially irradiate the whole body. Bone tumors cannot be excluded as a late effect with cerium. This contrasts to cesium. Yet the soft-tissue damage from cerium is more generalized than is the case with strontium, on the average. Current data do not allow direct estimates of risk of the several types of effects. It is hoped that future work will make such estimates possible. Until we have a true picture of comparative risk, we are probably likely to unintentionally over- or under-emphasize one type of effect compared to another.

E. Other Radionuclides

The enormous enterprises with tritium and the actinides have been amply discussed elsewhere in this book. We need only remember that tritium may sometimes be underemphasized in biological significance because of its generally low toxicity. The actinides, by contrast, have retained their reputation, developed very early, as highly toxic and especially potent carcinogens. There are no additional biomedical data that need summarizing here. In comparison to fission products, the actinides are not of concern in the early periods of fallout. It is in the long pull from both fallout and in waste disposal that their possible health effects become most important. There were some special environmental problems with plutonium, in particular, which we will need to review in the next chapter.

V. Summary and Commentary

The scare thrown into the biomedical community, as well as society in general, by the problems of fallout from nuclear weapons tests stimulated much expansion of research on the radionuclides in fallout. Some of it was primarily an expansion of the work on fission products described in chapters 6 and 8. Some of it could be regarded as essentially new. All of it was correlated with knowledge and ideas that were already appreciated but in need of very significant expansion. In all cases, the resources and personnel thrown into the effort were far above anything that would have occurred without the fallout scare.

At least seven new laboratories came into being, in part, at least, to attack various aspects of these problems by experimental means. The earliest was the Naval Radiological Defense Laboratory at San Francisco. This originated around the problems first appreciated at Operation Crossroads (chapter 12). Much of their work was very practical, but they also engaged in rather basic biomedical research, including aquatic biology. In fact, the laboratory became a center for several types of radiobiological work, developed a sizeable animal colony and research staff, and was very well equipped by the time of its closing in 1969.

The cattle with beta burns on their backs from the Trinity shot were the progenitor for a very considerable research effort at Oak Ridge. The organization was separate from the Oak Ridge National Laboratory. It was a cooperative effort between the AEC and the University of Tennessee Agriculture School. It was called the UT-AEC Farm and was the site of much laboratory research with strontium, iodine, and other fallout radionuclides. It was here that Cyril Comar and his colleagues worked out the so-called "observed ratio" (OR) approach for comparison of the metabolism of strontium with that of calcium and for other pairs of elements in plant and animal systems. The laboratory was later renamed the "Comparative Animal Research Laboratory" and the work proceeded without the single-minded devotion to fallout problems it had during its prime years. Much of what we learned about the discrimination between elements normally present in significant quantities in living organisms and their homologues was generated by work at the UT-AEC Farm and at Cornell University, where Dr. Comar transferred in 1957, as well as in work at Hanford.

The Laboratory of Physical Biology at the New York State College of Veterinary Medicine at Cornell University carried forward and expanded work on mineral metabolism of the type begun by Comar and his staff at the UT-AEC Farm. Both laboratories specialized in the use of large animals and devoted much attention to transfer into milk, across the placenta, the movement of radionuclides through food chains, and to fundamental radiobiology.

The fourth new laboratory developed around the problems of fallout was at the University of California at Davis. Its organization was described in chapter 8, but the results of its long-term feeding of strontium to beagles and of injected radium are described briefly in this chapter. There was little doubt that the distribution of effects in the beagle was not the same on a feeding regimen as after intravenous injection.

At least two major laboratories were developed anew by the U.S. Public Health Service in response to the problems of fallout. The first was the Southwestern Regional Radiological Health Laboratory in Las Vegas. This was a diversified program with laboratory work at Las Vegas and a field station for large animals and controlled ecological studies at the Nevada Test Site. It included work with fistulated steers, agronomy, and a major effort at methods for removing strontium from milk. All of this was in addition to their work in offsite

environmental monitoring described in chapter 12. In 1970, the laboratory came under the Environmental Protection Agency, and its program has gradually broadened to include nonradioactive contaminants of the environment.

At the Robert A. Taft Center of the Public Health Service in Cincinnati, a breeding colony for cats was established, and the metabolism and effects of strontium and iodine in the feline were studied. There were some contrasts with other species. There was also experimental work on freshwater biota. After a few years, this program was transferred to the Twinbrook facility in Rockville, Maryland.

Among the last of the new laboratories developed in the period we are reviewing were the Biomedical Program at the Lawrence Livermore Laboratory and the inhalation program at the Lovelace Foundation. The latter was directed to the metabolism and effects of inhaled fission products. However, fallout problems were not predominant in its genesis since there are greater potential inhalation problems from reactor fission products. Its work and results are described in chapter 9. By contrast, the program at Lawrence Livermore was originally centered on fallout problems, with special reference to Project Plowshare. This will be reviewed primarily in chapter 14, but was touched upon in chapter 12.

In addition to laboratories developed *de novo*, many of the established laboratories modified and expanded greatly their programs in areas related to the problems of fallout.

Some of the largest and longest experiments on the metabolism and effects of fallout radionuclides were developed at Hanford (later Battelle, Pacific Northwest Laboratories). There was a multigenerational study of strontium in miniature swine; studies of fallout radionuclides in adult, fetal, and juvenile mammals; and the transfer of pairs of elements in plants. This last produced results somewhat at variance with the OR approach used by Comar. All of this was in addition to the multigenerational experiment with iodine that was already under way before the fallout problems became pressing.

The continuation and expansion of the comparative toxicity experiment with mice at Argonne National Laboratory (chapter 8) could be considered, in part, a research response to the problems of fallout. At least the results became part of the fallout controversy as described in this chapter.

Brookhaven made contributions to the research needs of the fallout days by definitive work on mineral metabolism, especially using the whole-body counter. Much of the work involved man rather than animals. There was also a significant program involving plants.

The University of California at Berkeley, the seat of the original research on fission products, added a study of strontium metabolism in the rhesus monkey and later on actinides in the cynomolgus monkey. The latter is now reaching fruition.

Additions to the research programs also occurred at Rochester and Los Alamos, plus a unique mixture of field and glasshouse studies on plants and plant-soil interactions at the University of California at Los Angeles. In this case, the field studies were at the Nevada Test Site, the experimental work at the University.

The results of the new and of the expanded research efforts are described in the chapter, plus some generalizations on how the many experiments described in chapter 8 meshed with them. There is no doubt that we now have considerable information, perhaps more than for any of the common chemically toxic

pollutants, even lead, mercury, and cadmium as a result of research stimulated by the problems of fallout. The principal area of doubt concerns the risks of very low-level, long-term intakes of the fallout radionuclides just as in the case of external radiation. Also, it seems clear that strontium is becoming a benchmark for the beta emitters as radium became for the alpha emitters, except that all of the evidence for effects of strontium has been obtained from animal experiments rather than from human experience, for which we can be thankful.

Note 1(a)

Selected reports and publications in the biomedical area from the NRDL, San Francisco, California, especially pertinent to assessment and research on problems of fallout. Emphasis is placed on NRDL reports. Many publications are cited elsewhere in this and other chapters.

Note 4

- A. Formulas for placental discrimination (from Wasserman et al. 1957 and Comar and Wasserman 1960).

$$DF_{\text{absorptive}} = \frac{100 - F_{\text{Sr}}}{100 - F_{\text{Ca}}}$$

$$DF_{\text{urinary}} = \frac{(100 - F_{\text{Ca}}) - \left[U_{\text{Sr}} \times \frac{100 - F_{\text{Ca}}}{100 - F_{\text{Sr}}} \right]}{M_{\text{Ca}} + P_{\text{Ca}}}$$

$$DF_{\text{placental-dam}} = \left[\frac{M_{\text{Sr}}}{M_{\text{Ca}}} \right] \left[\frac{M_{\text{Ca}} + P_{\text{Ca}}}{M_{\text{Sr}} + P_{\text{Sr}}} \right]$$

$$DF_{\text{placental-fetus}} = \left[\frac{P_{\text{Sr}}}{P_{\text{Ca}}} \right] \left[\frac{M_{\text{Ca}} + P_{\text{Ca}}}{M_{\text{Sr}} + P_{\text{Sr}}} \right]$$

Where:

- $F_{\text{Sr}}, F_{\text{Ca}}$ = % of ingested Sr or Ca in feces
 $M_{\text{Sr}}, M_{\text{Ca}}$ = % of ingested Sr or Ca in dam
 $P_{\text{Sr}}, P_{\text{Ca}}$ = % of ingested Sr or Ca in fetus
 $U_{\text{Sr}}, U_{\text{Ca}}$ = % of ingested Sr or Ca in urine

B. Formulas for lactational discrimination (from Wasserman, Lengemann, and Comar 1958, and Comar and Wasserman 1960).

$$DF_{\text{absorptive}} = \frac{100 - F_{\text{Sr}}}{100 - F_{\text{Ca}}}$$

$$DF_{\text{urinary}} = \frac{(100 - F_{\text{Ca}}) - \left[U_{\text{Sr}} \times \frac{100 - F_{\text{Ca}}}{100 - F_{\text{Sr}}} \right]}{B_{\text{Ca}} + L_{\text{Ca}}}$$

$$DF_{\text{lactational-body}} = \left[\frac{B_{\text{Sr}}}{B_{\text{Ca}}} \right] \left[\frac{B_{\text{Ca}} + L_{\text{Ca}}}{B_{\text{Sr}} + L_{\text{Sr}}} \right]$$

$$DF_{\text{lactational-milk}} = \left[\frac{L_{\text{Sr}}}{L_{\text{Ca}}} \right] \left[\frac{B_{\text{Ca}} + L_{\text{Ca}}}{B_{\text{Sr}} + L_{\text{Sr}}} \right]$$

Where:

$F_{\text{Sr}}, F_{\text{Ca}}$ = % of ingested Sr or Ca in feces

$B_{\text{Sr}}, B_{\text{Ca}}$ = % of ingested Sr or Ca in body

$L_{\text{Sr}}, L_{\text{Ca}}$ = % of ingested Sr or Ca in milk

$U_{\text{Sr}}, U_{\text{Ca}}$ = % of ingested Sr or Ca in urine

Capsule Chronology

- April 1956** Project 56 carried out in Areas 11 and 5 (GMX) of Nevada Test Site (NTS).^(a) Four "safety shots" and 22 GMX shots. Biomedical interest is environmental contamination with plutonium. Long-term study proves decrease in availability for wind resuspension with time.
- 1957** Test Group 57 of Operation Plumbbob in Area 13 of NTS. A biomedical evaluation of hazards of the one-point detonation. Indicates that cloud passage dose is larger than that from residual environmental contamination. Acute and chronic phase out to 160 days in field. Air concentration of plutonium found to fall off rapidly with time (Rochester, Sandia, military). Data used for confirming surface contamination guidelines (military).
- 1958** Fission-product-release studies at Idaho Falls (Wilson, Boecker, Lie, Smith, Thomas at Rochester; Terry, Air Force; Idaho personnel). Uses melted fuel elements from reactors.
- 1959** Static tests of nuclear rocket at NTS (Kiwi). Several laboratories and services involved, but most of the biomedical data come from Langham at Los Alamos.
- 1960** Publication of data from TG '57' (especially Wilson, Thomas, and Stannard for biomedical aspects).
- 1961** SNAP (Systems for Nuclear Auxiliary Power) first used in space program. Continues through the present and includes sources on the moon and in interplanetary space.
- Project Plowshare begins. An ambitious program under the Atoms for Peace umbrella. Twenty-seven specific shots and large computational effort concerning the feasibility for digging a new transisthmus canal with nuclear explosives. Other "geographical engineering" efforts.
- 1962** Cratering event Sedan at NTS. Part of Project Plowshare. Followed up for several years (Essington, Gerber, Martin, Turner).
- 1963** Operation Roller Coaster approved. Joint U.S.-U.K. operation at Tonopah Test Range in Nevada. Implemented subsequently as a massive investigation of the nature and fate of plutonium aerosols physically, spatially, and biologically. Four separate tests. Termed the largest inhalation experiment ever performed under field conditions.
- 1964** SNAP device (SNAP 90 A, alias Transit 5-BN-3) burns up in atmosphere and injects 17 kCi of ²³⁸Pu. No biological hazard found since nearly all remains in stratosphere (Hardy, Krey and Volchok at HASL).
- Test detection shot in Mississippi.
- 1965** Amchitka Island, Alaska tests. Project Chariot. Much interest in arctic food chains.
- 1965-1968** Publication of Roller Coaster results (Wilson, Stewart, and Terry). Marked differences in biological behavior of plutonium aerosols depending on animal species and characteristics of aerosol. Burro considered best model for humans.

(a) For abbreviations and acronyms, see Appendix D.

- 1966 Contamination incident at Palomares, Spain. Massive clean-up operation and long-term study of inhabitants and environment (Spanish authorities, AEC, and military). Despite much wind-blown plutonium, inhabitants show little accumulation.
Salt dome test in Mississippi.
- 1967 Gasbuggy test in New Mexico. Gas stimulation experiment in Project Plowshare. Tritium is principal radionuclide contaminant.
- 1967-1970 ORNL reports on calculated doses and biomedical feasibility for constructing a new transisthmus canal with nuclear explosives (Cowser, Kaye, Rohwer, Snyder, Turner).
- 1968 Contaminating incident at Thule, Greenland. Extensive study of environmental contamination with plutonium (Danish authorities, AEC, and military).
Paper by Odland on military personnel working at Palomares.
Last announced cratering event in Plowshare series.
- 1969 National Environmental Policy Act passed.
Project Rulison test in Colorado. Second gas stimulation test in Plowshare series. Becomes grounds for litigation.
- 1970 Nevada Applied Ecology Group organized at AEC Operations Office in Las Vegas. Primarily to measure and evaluate long-term contamination of NTS, also make an inventory of transuranics (Dunaway and White). Much work done by contracts: (Soil sampling: Fowler, Essington, Gilbert; transportability of plutonium in biosphere: Au, Becket, Wildung, Garland; plant-soil interactions: Romney, et al.; grazing studies: Smith, et al.; modeling: Martin, Gilbert.)
- 1971 Stated that gas stimulation technology, e.g., Rulison type, could double the recoverable natural gas resources of the U.S. (Anspaugh et al., LLL).
- 1972 First annotated bibliography on environmental aspects of plutonium (Pfuderer, Oak Ridge) under NAEI contract. Many more follow.
- 1973 Project Rio Blanco test in Colorado. Third and last gas stimulation project in Plowshare series. Despite indications of low radiation hazard from the piped gas, public and industry acceptance of the technology does not develop.

Chapter 14

Special Environmental Test Projects

Overview

This chapter reviews a series of environmentally oriented test projects carried out largely in the decades of the 1950s and 1960s that had specific objectives outside the purview of those described in connection with the production sites (chapter 11) or fallout from nuclear weapons tests (chapter 12). They addressed urgent practical problems of the day. In some, such as the "safety shots," hazard evaluation was at the core of the enterprise. In others, biomedical studies were secondary to or shared priorities with engineering tests. The total commitment in dollars was large. This type of work does not come cheaply. The commitment of manpower from the biological and medical community was only moderate, however, partly because the military and industry supplied much technological help. Both commitments were largely justified, since results from several of the tests were at variance with predictions and, indeed, could not have been obtained in any other way. In a few instances, the biomedical findings probably helped to discourage further work on the project. In others, engineering problems were never licked, or interest faded and funds dried up before they could be solved. The personnel and expertise came primarily, in the Atomic Energy Commission family, from the Hanford Laboratories, Lawrence Livermore, Los Alamos, and the University of Rochester, the University of California at Los Angeles, and Oak Ridge; the military, e.g., Kirtland Air Force Base; industry, e.g., Sandia Laboratories, Convair-Fort Worth, and many contractors for specific jobs, plus the onsite contractors such as EG&G and Reynolds Electric; and the U.S. Public Health Service, later the Environmental Protection Agency, laboratories in Las Vegas, and at the Nevada Test Site.

The chapter begins with a review of the "safety shots" concentrated in Nevada (Project 56, Test Group 57, Project Roller Coaster), whose *raison d'être* rested on the possibility of plutonium contamination from accidental detonation of the high explosive charge(s) in a nuclear weapon, i.e., the so-called "one-point detonation." Also, what we learned from the accidents at Thule, Greenland, and Palomares, Spain, is touched on. This work made important contributions to the procedures and safety for handling and storing nuclear weapons. It also changed completely the first emphasis in hazard evaluation

from long-term residence in a contaminated area to events at the time of cloud passage. Also, it was learned that the activity level underfoot at a given location is not a reliable measure of what may be found in animals or plants, because it is where the air that is transporting radionuclides has been that controls its content, not the activity on the ground at the point of measurement. It is primarily ecological factors, the chemical form of the radionuclides and other processes that control the accumulation of radionuclides in living organisms.

The next subject is long-term follow-up of plutonium and related contamination at the Nevada Test Site as carried out by the Nevada Applied Ecology Group. This enterprise was both environmental and experimental, with work farmed out to several laboratories. Details of the Nevada Applied Ecology Group soil inventorying, soil-plant interactions, animal studies, including grazing and modeling activities, are given briefly.

The fission product release studies, centered on the planned nuclear-powered aircraft and carried out at the National Reactor Test Station (now the Idaho National Engineering Laboratory) in Idaho Falls, are reviewed. These involved melting down of "green" or "aged" fuel elements and exposure of animals and plants for subsequent pharmacokinetic studies. These again turned up phenomena not predicted by laboratory work.

Project Plowshare, one of the most ambitious of the Atoms for Peace plans, receives attention from the standpoint of biomedical and radioecological experimentation—field, laboratory, and computational. Included are the enormous efforts put into evaluation of the possibilities for excavating a new interoceanic canal in Panama or Colombia using nuclear explosives, the various actual cratering experiments at the Nevada Test Site, such as Project Sedan, and the joint U.S. government-industry experiments to stimulate release of natural gas from impermeable strata, i.e., Projects Gasbuggy, Rulison, and Rio Blanco. While it is difficult to find positive and succinct statements supporting such conclusions, the biomedical data from many of these events must have contributed significantly to the abandonment of the interoceanic canal project and perhaps also to the gas stimulation project, although the data did not indicate undue hazards with the latter. In this case, it seemed to be more an abhorrence of piping gas that had been made radioactive by man, no matter how slightly, into homes and industry.

The chapter ends with brief considerations of the biomedical aspects of radioisotope generators for electricity (Project SNAP) and the nuclear powered rocket and its reactor (NERVA and Kiwi, respectively). The former project has been quite successful operationally. Health hazards, projected and real, as measured from one mishap, appear quite manageable. By contrast, the nuclear-powered rocket was viewed with suspicion and relegated to potential use only in the upper atmosphere or in space. In addition, a special test in Mississippi and the extensive environmental work done in Alaska as prelude for some tests that never occurred are described briefly.

The research data accruing from these rather extensive projects uncovered important and interesting facts that had a major impact on the planning and characteristics of future experiments, indeed whole enterprises.

I. Background

The philosophy behind these projects requires consideration. They were expensive, demanding of manpower, and complex. In the eyes of some, they diverted

resources that might better have been devoted to controlled laboratory experiments. Nevertheless, there was considerable urgency to evaluate the potential environmental contamination problems of some of the devices, and they had to be tested anyway for engineering feasibility. Decisions could not wait for the results of slow multifactorial laboratory research. Furthermore, there were strong feelings, particularly in the military and the military applications groups in the Atomic Energy Commission (AEC) and the environmental scientists, that no laboratory experiment could reproduce the conditions of the field. This is probably true. However, it can also be argued that every field release is different, and what one finds in any one test may or may not apply to other events. With expense and other demands high, including the simple fact of contamination of real estate, albeit the most isolated of deserts, it is not practical to conduct a full spectrum of such tests. Results will always be incomplete. Some of the larger projects were able to utilize a series of events with very different potential environmental impacts. Nevertheless, the conditions for each test were very carefully planned to ensure the maximum content of information pertinent to the problems at hand. Rigid constraints were enforced regarding meteorological conditions, for example, and the event did not take place unless everything met the predetermined specifications. These did indeed maximize the chances for checking out the questions posed.

Sometimes, as we will see, the projects turned up with unexpected answers and raised new questions. These were probably among the most valuable results of these field experiments. Such results would probably have been missed entirely if only laboratory experiments and data had been employed.

On balance, it must be concluded that these projects made important contributions, despite the obvious problems of such research and the need for support that, by laboratory standards, was disproportionate to the amount of information gained. They had to be done anyway for many reasons.

Support came largely from the Department of Defense (DoD) and the AEC, but there was also some international collaboration. Personnel came from AEC and DoD laboratories in about the same proportion as for the weapons tests described in chapter 12.

The events with plutonium were described by Stannard (1973) in a general review of plutonium in the environment. This included both the planned projects and the two major accidents, the one in Thule, Greenland, and the other in Palomares, Spain. We will go into considerable depth here on the organization, plans, and results of the formal test projects and consider the two contaminating accidents briefly, especially for what they contributed in the form of research findings.

II. Safety Tests for Plutonium at and Around the Nevada Test Site

A. Purpose

These projects were developed around a single potential contaminating event: the release of plutonium (or in some cases, plutonium and uranium) from a nuclear weapon in case of accidental detonation of one (or more) of its high explosive charges. Such devices are constructed so that a nuclear reaction of any magnitude is virtually impossible under such circumstances. However,

much of the plutonium and uranium content can be (and has been) released to the environment by detonation of even one of the high explosive charges.^(a)

An elaborate protocol was set up for handling such devices to prevent accidents; but the military found it advisable also to set up guidelines for access to any areas contaminated with plutonium should such an event occur. Furthermore, teams with experience in measuring alpha-particle contamination in the environment, some of them utilizing personnel from civilian laboratories, were organized and could be brought to bear quickly in case of a "Broken Arrow" incident.

It was realized that most of the criteria employed were quite empirical and were based on scant amounts of solid information. Thus, it was decided to gather data by formal projects at the Nevada Test Site (NTS) centered first on the characteristics of the contamination (area, extent of distribution, particle size, mobility, etc.) and, later, elaborate tests of cloud behavior and uptake, distribution, retention, and possible effects of the contaminating plutonium in experimental animals.

Excellent reviews of the *raison d'être* and principal research problems involved in these projects were produced by Langham at Los Alamos (1968, 1969, 1971) after the work, which was initially done under high security restrictions, had been declassified.^(b) These reviews included general problems of plutonium contamination as well as these specific projects. Also, Langham was personally involved in both the Palomares and Thule incidents by acting as the principal biomedical consultant *in situ* for the United States. The Los Alamos group was intimately involved in delineating the problems and in planning details of execution of the tests. However, many other groups played major roles.

There were thirty-three events characterized as "safety experiments"^(c) listed in the report on announced U.S. nuclear tests from the Nevada Operations Office and Los Alamos, Lawrence Livermore, and Sandia National Laboratories (NVO 1982). These were not all actual weapons. They were frequently associations of plutonium and high explosives in various configurations. Most of them produced zero fission release, but a few produced yields from a few tons of TNT up to the equivalent of fractions of a kiloton. Fortunately, all of the experiments that involved biology had essentially zero fission yields. All but one occurred at or near NTS, with one (Scaevola) taking place on a barge at Enewetak. The last experiment listed officially as a "safety experiment" occurred at NTS in October 1958. The shots for the Roller Coaster Project, which will occupy our attention soon, were listed as "storage-transport" related projects, rather than as safety shots because their primary objective was the development of criteria for transport and storage of nuclear weapons.

The bulk of the work concerned physical measurements, especially soil contamination and the physicochemical behavior of the released plutonium and associated actinides. This is true even of the long-term follow-up studies. Only two of the projects included extensive investigations of biological aspects, viz.,

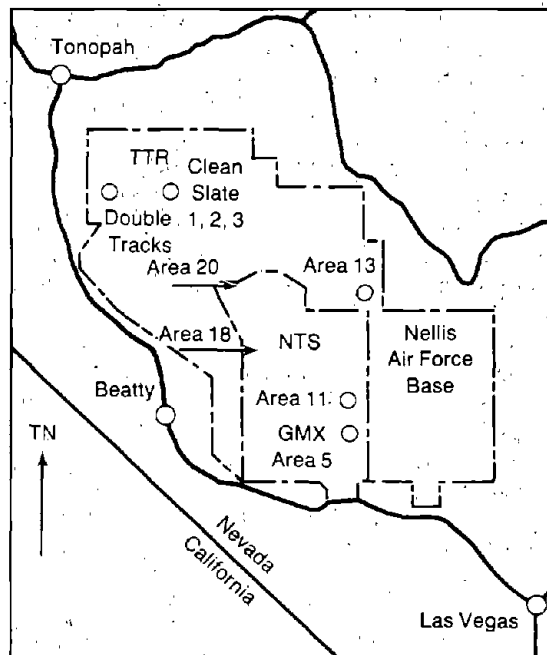

(a) Hence the term "one-point detonation."

(b) There was also a much-used classified document by Wright Langham, Payne Harris, and Ernest Anderson that we cannot quote.

(c) A safety experiment is defined in the quoted report as "an experiment designed to confirm a nuclear explosion will not occur in case of accidental detonation of the explosive associated with the device."

Test Group 57 of Operation Plumbbob and Operation Roller Coaster. Figure 14.1 shows the sites of most of the activities of interest. Details are given in the legend.

FIGURE 14.1. Map of Nevada Test Site (NTS), Tonopah Test Range (TTR), and the surrounding buffer region of the Nellis Air Force Range, in South Central Nevada. The areas involved are very large. The TTR was many miles from NTS. Project 56 activities took place in Area 11 (later referred to as "Plutonium Valley"). Test Group 57 was in Area 13, while Operation Roller Coaster took place at the points marked "Double Tracks" and "Clean Slate 1, 2, 3." The other areas designated were not involved very much in studies pertinent to this chapter. (Redrawn from Essington 1978.)

B. Project 56, GMX, etc.

Project 56 consisted of four shots done in Area 11 of NTS, two in December 1955 and two in January 1956. The purpose was primarily to test the vulnerability of current model weapons to one-point detonation. There was essentially no fission yield in two and on the order of one hundred pounds TNT equivalent in two tests (Johnson 1982).^(a) From the environmental standpoint, they were primarily useful in showing how the plutonium was spread, its behavior in air and soil, etc. There were fallout trays for collection and cement pads reinforced by air samplers, some of which were offsite. Otherwise there was nothing that could be tied into biological modeling and no overt biological work.

There were different configurations for the devices and thus different avenues of dispersal from total enclosure to essentially no obstruction. The objectives of the work were evidently met satisfactorily.

The reports of Project 56 remained classified for many years and were apparently gradually destroyed in the periodic housecleaning episodes that occur in government laboratories. Very little appeared in open publications. This author

(a) Johnson remarks that a "little fission helps because you are not put through the agony of 'hands and knees' alpha monitoring . . ."

is indebted to William Johnson, Sr. (cited above) and to Dr. Harry Jordan for a personal interview at Los Alamos (Jordan 1981) for reminiscences on the actual events. Fortunately, the long physical half-life of plutonium has made return visits to Area 11 possible and useful for checking out its persistence, any changes in mobility by processes of solubilization, its downward migration into the soil, the processes of resuspension by wind, and the ingrowth of ^{241}Am by the decay of ^{239}Pu .^(a) Later resurveys occurred under the aegis of the Nevada Applied Ecology group (NAEG) (which see).

The work of Project 56 and follow-up showed beyond question that plutonium becomes less available with time for resuspension by wind.^(b) This was pretty much a Los Alamos show. By a series of calculations based upon the findings of Project 56, lung models, and the like, the Los Alamos H-Division people came up with a figure for the maximum activity of plutonium that might be allowed without clean-up or evacuation around a Broken Arrow site. This was $100\text{ }\mu\text{g}$ of $^{239}\text{Pu}/\text{m}^2$ of surface. The figure has been largely attributed to Wright Langham and Payne Harris and seems to have been adopted, more or less verbatim, by the military (more of this in chapter 15). How it was derived appears to be lost in antiquity. The most quoted reference is a Los Alamos report by Harris, Anderson, and Langham (1956), but this author has not seen it for some years.

The so-called GMX shots were essentially chemical events, i.e., small chemical explosions that dispersed small quantities of plutonium. They were directed at "equation of state" physics studies. There were twenty-two GMX shots between December 1954 and February 1956. Their only biological contributions were through the soil-sampling program.

C. Test Group 57

There was considerable agitation for a much more extensive project than Project 56 to evaluate both the long-term and short-term hazards of the release of plutonium by a one-point detonation. In relatively short order, there evolved plans for a sophisticated study of the cloud dynamics and testing of fallout models, the behavior of the released plutonium in the air and in soil, ways to decontaminate various surfaces and vehicles, and a full-fledged biological experiment with both short- and long-term exposures. The Test Group was part of Operation Plumbbob, which took up most of the calendar year 1957. It began in early February 1957, with the shot occurring on April 24, 1957 at 0627, and the

(a) The work of Project 56 may have been classified, but the fact that someone was spreading plutonium around came to light through the Public Health Services' (PHS's) offsite surveillance work (see chapter 12). As Carter and Placák described (1956) at the AEC-DoD symposium on the shorter-term biological hazards of a fallout field, alpha contamination readings were obtained with fallout trays, with air samplers located in populated areas offsite, and a mobile air-sampler mounted on a trailer. Maximum contamination on a fallout tray was 10^5 d/min/ft^2 at a distance of about five miles from ground zero, but plutonium was detectable out to fifty miles. The portable air samplers showed plutonium out to one hundred miles. All of the readings were very transient and returned to background levels by the fourth or fifth day. They caused no concern regarding potential biological hazards offsite. Nevertheless, these facts indicate that quite significant quantities of plutonium must have been deposited onsite.

(b) This came from identical measurement techniques applied by the same people in repeat analyses at ninety days, one year, one and one-half years, etc.

field activities of the biomedical program were not completed until late October. The other field activities were completed much sooner.

The cloud dynamics and fallout model work included the use of balloons to suspend instruments above the array and was operated by the Sandia Corporation, which also did part of the longer-term air monitoring, surface monitoring, and the radiochemistry. The test director, James D. Shreve, came also from Sandia. The decontamination aspects were carried out by the U.S. Air Force. The biomedical program was assigned to the University of Rochester Atomic Energy Project with Robert H. Wilson as director of field operations, Robert G. Thomas as director of laboratory operations, and J. N. Stannard as general director for the biomedical program. The Armed Forces veterinary corps supplied two commissioned officers, Lt. Col. Roy Kyner, USAF, and Capt. Ralph Thomas, U.S. Army; an indispensable Sergeant First Class, Warren A. Gramley; and about twenty enlisted men to help handle animals. The thousands of plutonium analyses were done partly at Sandia in the laboratory of William Kingsley and partly by contractor organizations. Details of the planning, development of exposure cages and procedures, and of all operations are given in an unclassified report by Wilson, Thomas, and Stannard (1960).

The two distinct phases, acute and chronic, were handled somewhat separately. At the time of the detonation, twenty-four dogs were placed rather arbitrarily in a downwind array at five hundred, one thousand, and two thousand feet from ground zero. Also, about forty white rats were placed in cages on the ground for exposure to the passing cloud, and nine others were suspended in cages from the balloon rigging. Since the biological purpose of the acute phase was estimation of lung burden from inhalation of respirable particles from the passing cloud, recovery of most of the animals in the array occurred as soon as possible after it had been determined that there had been no beta-gamma radio-nuclides released in the shot. This retrieval was done, of course, in full protective clothing and respirators suitable for work in an alpha-contaminated field.

A few of the "acute dogs" remained in the field for several days after passage of the cloud. Some remained as long as thirty-six days (for details see Wilson, Thomas, and Stannard 1960). All rats were retrieved and sacrificed within four hours of the cloud passage.

It was not anticipated that the cloud passage would contribute much to the body burden because of the short period of exposure. In what turned out to be, in retrospect, a serious omission, no air samplers were placed at the animal stations for the acute phase.

Planning for the biomedical aspects of Test Group 57 concentrated mostly on the chronic exposure phase. It was reasoned that the windy desert environment would provide maximum opportunity for resuspension of the deposited plutonium and consequent inhalation by the animals. Thus, it was planned to place the animals for chronic exposure *after* the detonation to be sure to test only the uptake that might correspond to people living in a contaminated area, but not exposed to the cloud. The "magic" $100\text{-}\mu\text{g}/\text{m}^2$ line for plutonium on the surface was approximated by monitoring crews, and the animals were placed so as to be in the area from a maximum approximately ten times this nominal amount of surface contamination to a minimum of one-tenth of this figure.^(a) Thus, the

(a) The labor of defining the proper locations and placing the animals while the crews were fully suited-up in protective clothing and respirators was prodigious.

array was planned to put cages at grid points that would correspond roughly to 10, 100, and 1,000 $\mu\text{g}/\text{m}^2$ of plutonium surface contamination. There was, of course, horizontal spread along these lines to allow for shifts in wind direction. However, they were predominantly to the north and northeast of ground zero. Burros (nine) and sheep (ten) were added to the chronic exposure population to include animals that more closely approach the respiratory anatomy and physiology of humans than does the dog. A diagram of this grid pattern is shown in figure 14.2. The actual surface activities on the nominal 10-, 100-, and 1,000- $\mu\text{g}/\text{m}^2$ line were 2.6, 40, and 560 $\mu\text{g}/\text{m}^2$ as determined by the slow, laborious radiochemical analyses completed later.

The initial decisions had to be based on field-instrument measurements.

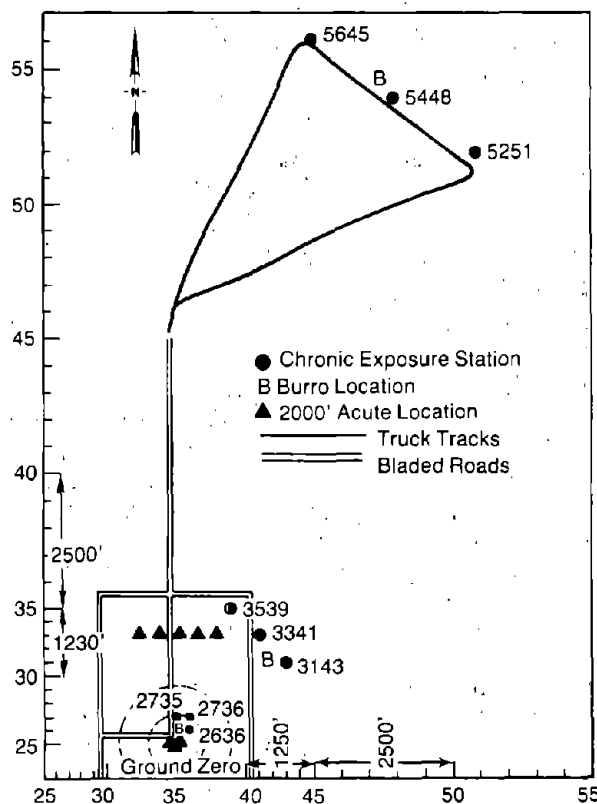

FIGURE 14.2. Layout of chronic array for Test Group 57 experiment. The 2,000-ft acute locations are also indicated for orientation purposes. The numbers refer to the grid coordinates for each cage complex. The first two digits refer to the north-south coordinate, the second two digits to the east-west coordinate. The nominal 1,000- $\mu\text{g}/\text{m}^2$ line was represented by 2735, 2736, and 2636; the 100- $\mu\text{g}/\text{m}^2$ line by 3539, 3341, 3143; and the 10- $\mu\text{g}/\text{m}^2$ line by 5645, 5448, and 5251. The array goes east of north because the prevailing winds are from the southwest. (Redrawn from Wilson, Thomas, and Stannard 1960.)

Animals were removed on a predetermined schedule ranging from 4 to 160 days after placement.^(a) The sheep and burros remained to the end of the exposure period. Some dogs were shipped back to Rochester at the close of the

(a) The logistics of maintaining animals in the field for so long a period needs comment. The Area 13 site was many miles from the supply base at Mercury and the usual route to it went directly across the areas where nuclear shots of Operation Plumbob were taking place. There were occasions when the dedicated animal-care crew drove several hundred miles to skirt the nuclear tests to get to Area 13 by a "back way."

160-day exposure period, and the plutonium burden in lung, rib, gastrointestinal tract, and both hilar and mediastinal lymph nodes in some was measured 360 days later or at 520 days after placement in the contaminated environment. Others were kept until it was clear that no long-term biological effects could be expected or detected, and they were then given to the Army.

Because the primary route of entry was expected to be inhalation, great emphasis was placed in the tissue analyses on lung, gastrointestinal tract, and the thoracic lymph nodes, but other tissues, particularly bone, were analyzed to measure redistribution from the lung.

The chronic phase had an elaborate program of air sampling. A cascade impactor operated by ground-laid cables from a central generator was planned for each fixed animal location. However, it was finally possible to operate only eight stations, one at each of the dog stations on the 10- and 100- $\mu\text{g}/\text{m}^2$ line and one at each end of the 1,000- $\mu\text{g}/\text{m}^2$ array. These were activated by Gast pumps. Rather than risk contamination in the field by removing and inserting slides and Millipore filters in the impactors in situ, the entire assembly was bagged and sent to Mercury for counting, and a fresh one was substituted. This occurred weekly. Technical problems prevented the air sampling program from getting into full operation until nearly a month after detonation, but it seems doubtful if this changed the basic results materially since the Sandia measurements were under way in the interim.

The results of this elaborate and laborious experiment can only be summarized here. There were some surprises, as will be evident below:

1. The animals exposed to the passing cloud showed much more plutonium in lung than expected. This was true also to a lesser extent for other tissues. Indeed, and despite the short period of exposure, the acute-phase animals showed generally higher body burdens of plutonium than even the longest-term chronic-exposure animals. In other words, it appeared that the short exposure to passage of the cloud was potentially more hazardous than chronic exposure to resuspended dust—totally unexpected.^(a)
2. The body and tissue burdens of the chronic exposure animals were much less dependent on the time of exposure than expected. Indeed, the readings were essentially random to the time of exposure. The expected gradual build-up in lung with time, for example, was not discernible.
3. As for correlation with location, the picture was mixed. Gastrointestinal tract and lung contents did seem to be fairly consistently higher at the nominal 1,000- $\mu\text{g}/\text{m}^2$ line than at 100 or 10 $\mu\text{g}/\text{m}^2$. This is illustrated in table 14.1A and B, which gives composite figures for all times. Note in table 14.1A that the relation to distance does not hold, however, for the lymph nodes. Neither did it appear to hold consistently for several other tissues listed in the table, but the amounts of plutonium were small.
4. The air concentration of plutonium fell off quite rapidly with time, $T_{1/2} = 35$ days. While the exact figure may be suspect because of the large variations, it is clear that the availability of plutonium for resuspension decreased rather rapidly. Thus, while total exposure increases with time, the increments

(a) This hazard may actually have been underestimated by the test, since, as Wilson (1984) commented, we have no assurance that the cloud-passage animals were at the location of maximum airborne concentration at ground level.

TABLE 14.1A. Test Group 57 "Safety Shot." Median Plutonium Concentration in Dog and Burro Tissues (disintegrations per minute per gram wet weight).

Exposure Condition	GI Tract Plus Contents	Hilar LN	Mediastinal LN	Lung	Femur	Rib
—Dog—

Location	Lung	GI Tract Plus Contents	Ratio GI To Lung
—Acute Dogs—			
500 ft	47.5	2,742	58
1000 ft	95	72,109	760
2000 ft	101	15,699	157
—Chronic Dogs—			
1000 $\mu\text{gm}/\text{m}^2$	36	2,660	77
100 $\mu\text{gm}/\text{m}^2$	1.6	496	310
10 $\mu\text{gm}/\text{m}^2$	2.5	112	45
—Chronic Burros—			
1000 $\mu\text{gm}/\text{m}^2$	254		
100 $\mu\text{gm}/\text{m}^2$	41.8		
10 $\mu\text{gm}/\text{m}^2$	27.8		
—Chronic Sheep (P + 32)—(a)			
1000 $\mu\text{gm}/\text{m}^2$	34		
100 $\mu\text{gm}/\text{m}^2$	7.0		
10 $\mu\text{gm}/\text{m}^2$	0.4		
	(5.2)*		

* Numbers comprising the median lung values at 10 $\mu\text{gm}/\text{m}^2$ included one 0 dis/min. reading. However, the analytical data show that a spill occurred with the 0 value. Therefore, values including and excluding (in parenthesis) this value are shown.

(a) "P" = Placement day.

Source: Modified slightly from Wilson, Thomas, and Stannard 1960.

get smaller. It is not surprising that there was much less time-dependence than expected. This contrasts markedly with the usual laboratory experiment employing multiple exposures.

5. The air-sampling data showed that the amount of plutonium in air varied much less with distance than did the concentration at the soil surface. While ground concentration contours varied from 2.6 to 560 $\mu\text{g}/\text{m}^2$, a factor of about 200, the air concentrations varied by only a factor of about seven, even with the great variations in wind velocity characteristic of the Nevada desert. The air appears to be something of an integrator and shows as much where it has been as where it is when sampled, not surprising when one thinks about it. Wilson, Thomas, and Stannard (1960) point out that the ratios of high- and low-level lungs and gastrointestinal tracts are not greatly different from the ratio of the corresponding cumulative air samples.
6. When the long-term air-sampler data became available (it took considerable time to do the radiochemistry and obtain reasonably quantitative data), it appeared that the maximum potential airborne hazard at ground level occurred at a considerable distance from ground zero, in fact, more than twice as far out as the most distant animal arrays! (Remember a similar phenomenon occurred with fission products, as noted in chapter 12. It is probably related to particle size distributions in the cloud.)
7. Dosage calculations for lung, based on measured tissue contents, were considerably different from doses that could be calculated using acceptable models and the results of the air-sampling data. No easy explanation was forthcoming for these animal-instrument discrepancies.

Other reports on the more physical aspects of this extensive operation are contained in the closely related Weapons Test (WT) reports, some of them referenced by Wilson, Thomas, and Stannard (1960) and by Stannard (1973).

The work of Test Group 57 bolstered the working criteria for transport and storage of plutonium weapons. However, the unexpected importance of the acute phase, the lack of good physical characterization of what the animals "saw" in this phase, the small number of animals therein, and the partial collapse of the notion that the resuspended dust would be the primary culprit led to many questions and some dissatisfaction with letting things stand as they were at the end of the Test Group 57 effort. Hence, another still more extensive project was put into the planning stages—Operation Roller Coaster. We will consider it next.

D. Operation Roller Coaster

1. The Plan

Operation Roller Coaster provided the climax for active field projects built around possible one-point detonations. As we have seen, the work of Test Group 57, while extensive, left many questions unanswered, some of them newly raised by the results. Many doubted the validity of the criteria developed. The British, who had to rely on U.S. test data, were especially concerned. Their high population density and intensive land use had already led to adoption of more stringent allowable ground contamination levels and more stringent allowable exposures than those adopted by the United States (Wilson and Terry 1965a). A number of joint U.S.-U.K. conferences were held beginning in the fall of 1961. The lack of definition of the aerosols most involved in the cloud

passage and the new importance of the cloud passage phase led to design of a joint U.S.-U.K. operation to try to tie down some of the loose ends. This was approved in January 1963 with the United States being the principal agent for the field work, but the United Kingdom making important contributions of men and equipment.^(a)

Operation Roller Coaster was perceived as "a massive investigation of the nature and fate of the plutonium aerosol, physically, spatially and biologically" (Wilson and Terry 1965a, p. 275). The events took place in an area of the Nevada desert even more isolated than NTS—an area northwest of NTS toward Tonopah (see figure 14.1) known as the Tonopah Test Range (TTR). There were participants from many quarters, military and civilian, as can be seen from the listing of reports to be presented later. Robert H. Wilson was the project officer with special responsibilities for the biomedical aspects, but the University of Rochester did not carry the major burden for these aspects as it had for Test Group 57.^(b) Indeed, the operation involved so many different organizations and people that the relative speed and high quality of the results must be marveled at. Obviously, coordination was very effective, as is possible in a military-type operation.^(c)

It was originally planned to repeat the work of Test Group 57 but on a much larger scale, both physically and biologically. However, it was not feasible to mount animal studies for the resuspension phase on so large a scale. The potentially greater hazard of the cloud passage phase led to a decision to concentrate the animal exposures on this. Resuspension phenomena, which were studied over a 160-day period, were studied by air-sampling instruments alone.

There were four detonations in the Roller Coaster operation under code names, "Double Tracks" and "Clean Slates I, II, and III." Double Tracks was arranged to minimize the entrainment of nondevice constituents into the cloud by firing on a large steel plate placed on a larger concrete pad both in a 100-ft circle of stabilized desert soil. There was a 78-mi² instrument array extending more than nine miles downwind. Clean Slate I simulated an open storage or transport accident, while Clean Slates II and III were fired in typical high-explosive magazines. The assumption had been made in the United States that a cover of earth would reduce the concentration and modify the aerosol of plutonium. Each of these Clean Slate shots had extensive instrumentation like Double Tracks. However, the major biological involvement took place in Double Tracks plus limited participation in Clean Slate II.

The animal studies of Operation Roller Coaster were the "largest inhalation investigation ever performed under field conditions," (Wilson and Terry 1968, p. 23) with 98 dogs, 154 sheep, and 98 burros, including controls (22 sheep, 14 dogs, and 14 burros). The increase in large animals over Test Group 57 was to provide more data from animals with greater potential applicability to humans than the dog has.

Reports of Operation Roller Coaster are relatively numerous, but only a few are generally available. There were many interim and progress reports, since all

(a) The British have long been strong in the areas of air sampling, aerosols, and meteorology and supplied particular help in these areas and much in the general planning.

(b) T. T. Mercer provided assistance with the aerosol evaluation, P. E. Morrow with interpretation of the biological results, and A. M. Dutton provided statistical analyses. All of these were from the University of Rochester.

(c) Regarding U.K. participation, Wilson and Terry (1968) mention especially A. Robson, R. Carter, and D. M. C. Thomas in addition to their coauthor, K. Stewart.

concerned were anxious to use the results as soon as possible. For our purposes, four documents, two of them already cited, provide the most pertinent biomedical information: the University of Rochester Atomic Energy Project Report by Wilson and Terry (1965b); the published paper at the symposium on inhaled particles and vapours, also by Wilson and Terry (1965a); a POR-WT report from the Defense Atomic Support Agency by Wilson and Terry (1968); and a final evaluation from the U.K. Atomic Energy Research Establishment (Stewart and Wilson 1968). Other more or less complete reports in the POR-WT series (i.e., joint U.K.-U.S. efforts that had "POR" designation, that stood, I believe, for "Project Officer's Report") were not specifically oriented to biology. They are listed as note 1 at the end of this chapter. The installations and personnel involved are listed there along with the other information.

The four main biomedical reports were not mutually exclusive. However, each has information not found in the others. Even though most of the documentation is in report literature and little in open publications, it cannot be said that this operation suffered, as did Project 56 and to a lesser extent Test Group 57, from inadequate reporting of some aspects. Nevertheless, the reports form a somewhat disparate mass that has not been graced by a concise overall summary. In the section to follow, we will consider very briefly the biological operation and the conclusions therefrom.

2. The Biological Experiment and Aerosol Support

Since the emphasis was to be placed on exposure during cloud passage, an entirely different mode of exposure for the animals was devised compared to Test Group 57. Instead of fixed placements, the animals were positioned on farm wagons (thirty of them) with either cages for the dogs and sheep or stanchions for the burros. These wagons could be moved along the designated arcs in the event of small changes in wind direction, which helped to remove some of the constraints on meteorology at the time of the shot. Also, to minimize ingestion by licking of fur, animal clothing was designed of muslin sheeting held in place with upholstery tape. These shrouds were found by preliminary tests to greatly reduce the noninhalation components of the exposure. They also simplified greatly the process of decontamination after the shot.

All of this was good for the experiment. Nevertheless, it generated a preshot procedure of considerable magnitude, viz., shroud over three hundred animals, load them onto thirty farm wagons, draw the wagons several miles from the base of operations to the shot site, place the wagons on the various arcs, and be prepared to change location up to minutes before shot time. Obviously, a fairly long and intensive training period was required for all hands, human and animal, to make such a program work.

Each wagon carried a Casella Mark II cascade impactor and a battery-driven Austin pump. In addition, some wagons had total air samplers (Mark I), Gelman disposable samplers, and Casella impactors with nuclear track stripping film. Every effort was made to have the samplers as close as feasible to the animals' noses.

Full details of these preparations and the shot-time, as well as those after the shot operations are given by Wilson and Terry in the University of Rochester report (1965b).

Although the intent was measurement of pick-up by the animals from cloud passage, the measurement schedule for the animals was quite long. It was intensive in the first month, but some animals were not sampled until three years

after the shot to check on retention factors. Over two thousand plutonium analyses were generated by this segment of the operation alone. The results, naturally, did not appear overnight.

3. The Results

Despite every attempt at its avoidance, random variability was as inherent in this experiment as the earlier ones. However, the sheer mass of data made the discernment of trends less irksome.

The results that came largely from the reports of Wilson and Terry (1965a,b) are summarized below:

- a. The aerosols were well characterized thanks especially to the expert contributions of the U.K. participants. Fairly large particles frequently contributed sizeable fractions of the total activity. Nevertheless, the early analyses of lung burdens showed close relationships to the information from the air samplers. "An animal is a competent sampler" (Wilson and Terry 1965a, p. 281).
- b. Initial deposition was about 23% of the respirable aerosol in dogs, about 11% in sheep, and about 18% in burros.
- c. Short-term clearance half-times were about four days for dogs, five days for sheep, and about ten days for burros.
- d. The sheep cleared much more plutonium by fast component kinetics. Thus, the amount of plutonium left for long-term clearance differed considerably among the species: 67% of the initial burden in dogs, 5.1% in sheep, and 22% in burros.
- e. The clearance kinetics for the Clean Slate II shot, which had much more inert dust, were different. Much more was cleared by dogs and sheep in the first seven days (Wilson and Terry 1965a, p. 285). As a result, the remaining lung burdens at seven days were only 5.5% of the respirable aerosol for Clean Slate II versus 15.9% for Double Tracks in the dogs and 0.4 versus 2.1 in the sheep. The organizers of the project had occasion to wish that they had been able to devote as much attention to these differences and aerosol-animal interactions as they did to Double Tracks, since they could influence hazard evaluations.^(a)
- f. The findings indicated that neither animals alone nor samplers alone would have sufficed to describe the respiratory hazard. Yet, the relatively good agreement between the two contrasts with the earlier tests and with much industrial hygiene experience.
- g. Mean radiation doses to infinite time for the three species studied ranged, for the aerosol of Double Tracks, from 0.96 rem in the dog to 0.08 rem in the sheep. The extrapolation to humans was 0.3 rem.
- h. There was little evidence of build-up of plutonium in tissues other than lung, and possibly respiratory lymph nodes. Thus, for this exposure, the lung appears to be the critical organ.

In the final evaluation (Stewart and Wilson 1968), the same basic points were confirmed, but there was much more: (1) on the kinetics of lung clearance, including the fact that a power function fits the data; (2) on the reliability of the characterizations; (3) on the point that the patterns of PuO₂ behavior in the

(a) This may be a non sequitur since the tendency is always to choose the most conservative case, and that would be the cleaner aerosol for Double Tracks, which was studied most extensively.

dog seen in this field experiment are very similar to those found in laboratory experiments; and (4) showing that the results from each animal species form a consistent set, i.e., the differences are not random. There was a tendency to view the burro as the best model for humans.

The difference between Double Tracks and Clean Slate II aerosols led to calculation of a factor of about three difference in the ten-year dose to lungs, with the Double-Tracks-type aerosol the higher.

In all the reams of data and discussion, it is hard to find a simple succinct statement from the investigators that Operation Roller Coaster did or did not confirm the importance of the cloud passage uptake and doses versus those from inhalation of resuspended material as drawn from the work of Test Group 57. However, since the cloud passage data are used for the calculation of dose, the discussion of hazard, and development of criteria, we must assume that the answer to this question was affirmative, although the planning was such that little else could be expected.

4. Comment

Plutonium radiochemistry is a slow process. It appears that one reason there seems to have been no grand finale in the reporting and analysis of either Test Group 57 or, especially, Operation Roller Coaster, is that there are still data requiring analysis. A letter from R. G. Thomas to R. H. Wilson (Thomas 1981) raises the question of what may or may not be waiting and also refers to the many soil samples taken by the University of California, Los Angeles (UCLA) team (especially Kermit Larson) in Area 13 that remain unanalyzed. We will see in a later section that conscious attempts have been made to go back over these contaminated areas (see the section on the NAEG). Yet, there seems to be some possible unfinished business from these two major operations.

E. Palomares and Thule

The Palomares and Thule incidents were accidents, not planned projects, and thus were not "Safety Tests." Yet, they need to be mentioned in this review. The one at Palomares, Spain, occurred on January 17, 1966. As a result of a refueling accident (collision) involving a B-52 bomber and a KC-135 tanker over the Mediterranean Ocean, four nuclear weapons were released from the bomber. Two were recovered intact, one from the Mediterranean about five miles offshore and one from a dry riverbed east of the Spanish village of Palomares (population about 1,000), on the coast. The other two underwent high explosive detonation, one at the east edge of the village, the other about one mile to the west. With a thirty-knot wind blowing out of the west, the dust containing ^{239}Pu , ^{234}U , and ^{235}U travelled across irrigated fields at the edge of the village in the one case and over truck garden areas just outside of town in the other. There was no nuclear yield in either.

The Thule incident occurred on the ice near Thule, Greenland, when an on-board fire forced ditching of a B-52 aircraft on January 21, 1968. Again there were detonations of the high explosive charges and contamination of the environment with plutonium, but no nuclear yield.

As mentioned earlier, these internationally important events were described briefly in an open literature publication by Stannard (1973). Much more detail is hidden away in the general discussions of plutonium contamination of the environment by Langham (1968, 1969, and 1971), in a trip report concerning his

return visit to Palomares and the collaborative efforts with the Danish at Thule (Langham 1972); and, for Thule, a special edition of the journal *USAF Nuclear Safety* entitled, "Project Crested Ice" (USAF 1970).^(a) The primary actions were to remove as much of the plutonium as possible from the surface and ship it back to the United States. Residual contamination at Thule was minimal since the plutonium that was not removed was gradually diluted into the sea. However, there were full-fledged examinations of biota and an extensive ecological program managed primarily by the Danes (Aarkrog 1971a,b; 1977), and by W. C. Hanson of the Hanford Labs (1971, 1972, 1975).

Langham (1972) describes the continuing work at Palomares carried out largely by a joint effort of the Junta de Energia Nuclear Division de Medicina y Proteccion headed by Dr. Eduardo Ramos, with equipment and operational support from the AEC. After the clean-up of the most contaminated area,^(b) the project settled down to periodic surveys of the environment and occasionally of the inhabitants. Long-term contamination levels of humans or environment have not been sufficient to cause real concern. The levels of airborne plutonium and uranium within the village were consistently below the maximum permissible concentration (MPC) (Iranzo and Salvador 1970). Samples nearer the sites of impact recorded maximum values of gross alpha activities above the MPC on fourteen occasions in the second half of 1966 and in 1967. The MPC was exceeded by a factor of ten on three days. These were during periods of high winds and much resuspension of the deposited radionuclides. Interestingly, the incidence of measurable uranium in the air exceeded that of plutonium; 30% of the samples showed no trace of plutonium, while only 3% showed no trace of uranium.

This work is continuing, albeit at a relatively low level.^(c) Fortunately, both of these incidents occurred in areas of low habitation density. Unfortunately, for the measurements, the area around Palomares happens to have one of the highest alpha-particle backgrounds in Spain, and the low-level measurements easily got lost in it.

Finding more detailed technical evaluations and their contributions to internal emitter research and hazardous analysis is not easy. The joint Spanish-U.S. reports and Spanish in-house reports would be useful, but are not readily available. The most convenient summary for the technical reader of the work done at Palomares over the first several months is a paper by Odland et al. (1968)^(d) given at the seventh Hanford biology symposium (see chapter 8 for these symposia) and the International Radiation Protection Association (IRPA) report by Iranzo and Salvador (1970), which concerns longer periods. The results reported

- (a) The author has copies of these documents that he would be glad to make available to interested readers. They are unclassified. There are also book-length descriptions of the events themselves and much in news magazines of the day (see Odland et al. 1968).
- (b) The ugly scar left on the fragile semiarid landscape, from the clean-up operation, impressed Langham as the most significant long-term result of the incident.
- (c) It was the author's privilege to meet Dr. Emelio Iranzo, Dr. Ramos's colleague in the Spanish operations, at the 1984 meeting of the Health Physics Society and to be informed that the work is still under way.
- (d) This paper gives rather complete references to descriptions in the popular press (*Business Week*, *Commonwealth*, *Life*, *Newsweek*, *Saturday Evening Post*, *Saturday Review*, and *U.S. News and World Report*) and reports from the PHS. A book-length description by Lewis (1967) is also cited.

by Odland include analysis of urine samples, nose swipes, water from various sources, such as the Mediterranean Sea and shower effluents, and radioactivity in soil and on vegetation samples. The urine samples came primarily from Air Force, Army, or Navy personnel involved in the clean-up operations. Only 38 out of 1,586 were other, and it is not clear whether or not these were residents. (Probably the prime source of data for the residents is in the Spanish literature, and this contained mostly long-term concentrations in air.) The plutonium analyses were done, for both initial and resamples taken several months later, by the U.S. Air Force Radiological Health Laboratory. Systemic body burdens of plutonium were calculated by the Langham equation for a single acute exposure (Langham 1956; for further discussion see chapters 7 and 16).

Of the 1,586 urine samples analyzed for the acute phase operations, 20 showed calculated body burdens greater than the maximum permissible, 422 showed plutonium concentrations between 0.99 and 0.09 of this value, 537 showed values between 0.09 and 0.009 of the above, and 607 showed calculated body burdens less than 0.009 of the maximum permissible. When we consider that these came from a hastily gathered group of personnel brought in for the acute phase of the operation, such a distribution of body burdens may be considered as satisfactorily low. However, these individuals wore protective clothing and took precautions that an uninitiated, untrained resident might not.

The nose swipes in the Odland work were negative, and the amounts in vegetation (e.g., tomatoes) were lower than reported in some of the magazine versions. However, the crops were condemned anyway.

The Air Force operated a resampling program for urinary plutonium content involving 422 personnel; all but 7 of them military. There were 6 cases with greater than 10% of the allowable systemic body burden, 213 were between 1% and 10%, 39 less than 1%, and 164 below the limits of detection.

One individual died during the study, of causes unrelated to plutonium exposure. The plutonium content of lung was about 500 pCi, calculated for the whole lung, while the last urine sample showed no detectable activity. This suggests the possibility of insoluble deposits of plutonium in lung and the virtues of resurveying the group with whole-body counters.

In view of the probable lack of protective actions taken by the Spanish residents and the airborne concentrations of alpha activity reported (e.g., by Irazzo and Salvador), it is surprising that there have not been reports of significant body burdens in any of these individuals. It can only be speculated whether this means that the levels were consistently low, the necessary measurements difficult, or not done, or the reports not generally disseminated. It is also surprising that measurements appear not to have been made in the indigenous animals and that animals were not brought in as stand-ins for humans (Wilson 1984).

The plutonium at Palomares does not seem to have descended very far into the soil; perhaps to be expected in a semiarid climate. Population and commercial pressures are prompting the inhabitants to expand gardening activities ever closer to the contaminated area (W. J. Bair, personal communication, October 1985). This makes it essential that the monitoring and survey activities be continued. It even augers for possible pressure for more removal of surface and near-surface soil for disposal.

Further follow-up of Palomares is reputed to be under way by personnel from several American laboratories under the Department of Energy (DOE): Los Alamos National Laboratory (LANL), Lawrence Livermore National Laboratory (LLNL), Oak Ridge National Laboratory (ORNL), as well as DOE Headquarters.

and by the Spanish authorities (e.g., Iranzo). No information has appeared that would change the conclusions drawn above.

Similar summaries of personnel monitoring for the Thule event, from both Danish and U.S. sources, are contained in *USAF Nuclear Safety* cited above. However, few quantitative data are given there. The emphasis is more on the environment. This is as it should be by the circumstances of the event, and much important information is contained in this review. A succinct summary and analysis of the work of Project 56, Test Group 57, and Operation Roller Coaster and how this work made it easier to react effectively to the accidents at Palomares and Thule were written by Harry Jordan at Los Alamos. His summary refers to some of the classified reports from the Nevada operations and gives also details on the contents of the Air Force document, "Project Crested Ice," cited above (Jordan 1971).

A resurvey of eight locations near Thule was carried out in 1974 (Hanson 1980) as part of a general review of the concentrations and inventories of ^{137}Cs , ^{238}Pu , and $^{239, 240}\text{Pu}$ in soils, lichens, and animals from northern Alaska and Greenland. Average inventories of $^{239, 240}\text{Pu}$ of Thule lichen communities, not directly contaminated by accident debris, were not significantly different from those in Alaska lichen carpets in 1968 and 1974, respectively. Thus, the Thule area was no higher six years after the incident than other Arctic areas possessing the unique lichen step in the food chain. Soil samples contained about 10^{-15} Ci of $^{239, 240}\text{Pu}/\text{g}$.

More details of the Thule ecological work can be found in publications by Aarkrog (1971a,b; 1977) and by Hanson (1971, 1972, 1975). These papers concern primarily the transport of plutonium in the subject ecosystems and are more appropriately considered as part of chapter 15. Much hinges on the $^{239, 240}\text{Pu}/^{137}\text{Cs}$ ratios.

III. Long-Term Follow-Up— The Nevada Applied Ecology Group

A. Genesis

In 1970, the AEC established an organization known as the Nevada Applied Ecology Group (NAEG) whose purpose included the following objectives:

1. Determine how and to what extent radioecological processes had redistributed plutonium and determine its uptake and food-web pathways in the biota of the NTS.
2. Guide and coordinate ecological, radiation monitoring and other environmental programs necessary to support continued nuclear testing activities.
3. Provide the mechanism to effectively comply with the requirements of the National Environmental Policy Act (NEPA) of 1969.

The program was planned and administered by a small scientific staff based at Nevada Operations Office (NVO). Principals in developing and administering NAEG were Jared Davis and Ernest Campbell, with the enthusiastic support of the NVO General Manager, R. E. Miller. Later the program was administered by Paul Dunaway and M. G. White, under the NVO General Manager, General M. E. Gates. Funds for the program were distributed to many laboratories through the NAEG operations. Prime among these were: the AEC family, the Pacific Northwest Laboratory (PNL), Battelle Columbus Laboratory, LANL, LLL, UCLA, ORNL, the AEC's Health and Safety Laboratory (HASL), New York, and

National Reactor Testing Station, now the Idaho National Engineering Laboratory (INEL); and outside of AEC, the Environmental Protection Agency (EPA) and Air Resources Laboratory, National Oceanic and Atmospheric Administration (NOAA), Las Vegas and NTS, Nevada; the University of Nevada at Las Vegas and service contractors such as REECO and Rockwell, Hanford. Many others joined for specific tasks.

B. The Problems and Mode of Operation

The scientific problems attacked were varied. High priority was given to soil analyses. There was much interest in what had happened to the plutonium in the years since the shots and whether or not the solubilization processes demonstrated in earlier laboratory and field research lived up to expectations in a larger-scale, larger-area study. There was also interest in the nature of the soil-plutonium binding processes, both physical and chemical; the increasing role of americium, the processes of resuspension by wind (which we will discuss in chapter 15), and how all of these could be brought to bear on hazard analysis. An enormous effort was put into statistical analyses to guide the soil sampling procedures for example and for interpretation of the data.^(a)

There was also much work with grazing animals and native animals, including uptake and transfer from vegetation, the construction of models for the possible intakes by and doses to humans developed from the accumulated data, and some very cogent laboratory investigations of specific points raised by the findings in the field. Finally, as momentum accumulated for the development of a full-scale information repository at Las Vegas, the NAEG entered into the work of the Information Center (see chapter 12). One of the earlier steps was a selected annotated bibliography on the environmental aspects of plutonium prepared by the Division of Technical Information, USAEC and spearheaded by Helen Pfuderer with guidance from M. G. White and others (e.g., ORNL 1972 with many updates; and 1978).

The various individuals and laboratories engaged in work for the NAEG program labored at their home institutions. Communications were handled by periodic NVO reports and an annual symposium, usually held in Las Vegas, that brought the principal investigators together for in-depth progress reports and discussion of plans. There was also an advisory committee for the general operation and several advisory committees for specific areas of research. We will discuss a few areas of special pertinence to this chapter presently. A selected list of reports is given as note 2 at the end of this chapter.

Before proceeding, however, we should remark that one of the prime early objectives of the NAEG, *not spelled out in the official raison d'être*, was to establish an inventory of the transuranics present at NTS and adjacent sites. Was there a sufficient amount of plutonium and the transplutonics to warrant clean-up measures? While Areas 11, 13, GMX, Tonopah Test Range^(b) are now among the more unlikely places for human habitation, it was argued that some day cheap irrigation water (desalinated sea water?) and the pressures of world population might change all that. People might live and grow crops in the midst of these long-lived radioactive materials! Thus, the inventory in the soil, its

(a) Until one reads these extensive compendia, it might have been thought that digging a suitable soil sample would be a simplistic if back-breaking process. Not so! It is a highly technical affair.

(b) Tonopah itself has a population of a few thousand and is growing.

availability, and the amounts found in grazing and indigenous animals and in vegetation assumed more than academic significance. We will review some of the key findings in the light of this erstwhile improbable environmental question.

C. Soil Sampling

The soil sampling program of NAEG was designed initially by the people at Los Alamos. Eric B. Fowler, whom we have already met, became chairman of the Soil Sampling and Analysis Committee, which was responsible for the plans and conduct of a radionuclide inventory study at five sites: Project 57 in Area 13; GMX in Area 5; Sites A, B, C, and D in Area 11; Clean Slates I, II, and III at TTR; and Double Tracks at a site adjacent to the Tonopah Range (see figure 14.1). From the beginning, R. O. Gilbert from PNL collaborated in the statistical design of the work and analysis of the data. Essington (1978) gives a good summary of the historical development of the soil sampling programs.

"Safety shot" sites were sampled intensively for ^{238}Pu , $^{239,240}\text{Pu}$, ^{234}U , ^{235}U , ^{236}U , ^{238}U , and later ^{241}Am . Detailed soil sampling was done by laborious and carefully designed procedures, followed by wet chemistry analyses. This takes much time. There was, in addition, in situ measurement of soil activity with a moderately portable instrument (Field Instrument for Detection of Low Energy Radiation [FIDLER]), also by Geiger-Müller and alpha survey measurements. However, the area was too large to be covered in detail on foot. Therefore, airborne gamma-radiation surveys were included. Under proper circumstances these could pick up the 60-keV gamma radiation from ^{241}Am and thus any "hot spots" missed in the other work could be detected and ground crews dispatched to check on details.

Among the earlier reports was a series of papers from NAEG-supported laboratories at a symposium sponsored by the International Atomic Energy Agency (IAEA) on transuranium nuclides in the environment held in San Francisco in November 1975. Despite the interest in the total inventory, these papers give it scant overt attention. Much more is said about movement in soil with time, chemical form, particle size, contours of distribution, etc. Only one paper addressed the central problem openly. Gilbert et al. (1976) reported on the inventory of several nuclides and gave an estimated inventory of $^{239,240}\text{Pu}$ in surface soil at one site (designated "A") in Area 11. It totaled about 0.035 Ci in three strata. There was much more uranium, but much of it came from natural sources. Other data, including inventory of other sites, were shown at later annual NAEG meetings and in publications. However, any composite figures for the total inventory appeared to be almost impossible to assemble. If they were, they would probably be classified. Nevertheless, we can find the trend of thinking several years after NAEG began operations in a partly philosophical, partly technical paper from the UCLA group (Wallace and Romney 1978). Their answer to the clean-up question is shown as part of their recommendations, quoted below:

Relatively little hazard exists with the Pu present at the old safety-shot sites in Nevada because so little human activity occurs or is likely to occur there, because the grazing potential of the amount of land in question is so negligible, and because no irrigation schemes for the area are likely for decades or centuries. It seems, therefore, that it would be valuable and profitable in behalf of mankind to obtain more of the answers possible from the presence of Pu in the natural desert environment. (Wallace and Romney 1978, p. 124)

Thus, the decision regarding clean-up was resolved in favor of no action for the present. The need for gathering more information took precedence. The quoted paper and its bibliography present some of the ideas about possible clean-up methods and their relative impacts should the decision be made to undertake it. Other aspects of the work with soils can be illustrated by the following:

1. Essington et al. (1976) showed from examination of over seventy individual soil profiles that there can be both smooth leaching of the transuranics and accumulation within specific zones; also, that large amounts can be found in the deepest profile.
2. Plutonium at NTS is predominately (50% to 70%) associated with coarse silt, 20 to 53 μm (Tamura 1976).
3. Much information was gathered that showed that microorganisms can contribute significantly to bioavailability and transport of plutonium in the environment. For example, plutonium went into the spores of the bread mold (*Aspergillus niger*) and could be transported to other soil fractions or the biomass by this route.^(a) This phenomenon was described at the IAEA symposium by Beckert and Au (1976) and in more detail at the 1978 NAEG meeting (Au and Beckert 1978). The work by NAEG confirms and extends the similar findings reported in chapter 13.

The Battelle people were also finding effects of microbiological processes on the behavior of transuranic elements in soils, plants, and animals, as was mentioned briefly in chapter 13. A useful review is contained in the book by Hanson, *Transuranics in the Environment* (Wildung and Garland 1980).^(b)

4. Much more was done with soils, including ideas on how rapidly the downward migration occurred, the bearing of the findings on protection criteria and sampling of many of the nuclear detonation sites, all of which we will have to pass over here, except to recommend that the reader peruse the list of NAEG reports in note 2 and the references in those papers.

D. Plant-Soil Interactions

Work on plant-soil interactions was largely done in the laboratory and followed closely that reported in chapter 13 even to having it concentrated at UCLA (Romney, Wallace, and Kinnear 1978). Support for the work came from NAEG because of the importance of knowing more about root uptake to answer the question of the need for cleanup. The results confirmed those discussed in chapter 13.

E. Vegetation

An overview of the findings with vegetation can be gleaned from the abstract of a paper by Romney et al. (1976) given at the IAEA symposium.

- (a) *Aspergillus* was especially useful since the spores are well above the growing mass of mycelia and can be harvested with little danger of contamination from soil or other organisms. There is reason to suppose that many soil microorganisms contribute to such processes.
- (b) Much of this was laboratory work or was done onsite at Richland and, thus, is not entirely associated with the NAEG effort.

Vegetation Studies in aged plutonium fall-out areas showed variations in the $^{239,240}\text{Pu}$ and ^{241}Am contamination levels attributable to differences in the amounts of resuspendable particulate material superficially entrapped upon plant foliage. There was reasonable agreement between the mean activity levels in vegetation and soil samples collected across different activity strata defined by FIDLER survey instrument within each fall-out area. The ratio of vegetation Pu to soil Pu tended to increase, moving out from higher to lower activity strata, which might reflect the increasing proportion of finer particulate material initially deposited in fall-out debris at greater distance from ground zero. The Pu/Am ratio was reasonably constant for vegetation samples collected from a given fall-out area. This ratio, however, varied among separate test events, primarily as the result of differences in the ingrowth of ^{241}Am within the aged source materials. Inventory estimates indicate that standing vegetation contributes a rather insignificant portion of the total contaminant remaining in these aged fall-out areas. (Romney et al. 1976)

Details were added in further work but nothing fundamentally different.

F. Grazing Studies

Probably some of the most pertinent information for biomedical evaluations came from the grazing studies carried out by the EPA Environmental Monitoring and Support Laboratory in Las Vegas and its branch at NTS,^(a) as described in chapter 13 and by Smith, Barth, and Patzer (1976) and Smith (1978, 1979). The first work involved only seven cows, four calves, three fetuses, three goats, three foxes, one jack rabbit, and one coyote; however, the later studies were much more extensive. They even involved the fistulated steers described in chapter 13. The studies presented a wealth of information. Since the cattle were restricted to the contaminated area, whereas the wild game had a much wider range, the cattle had higher contents of actinide nuclides than did the wild game.

Smith (1979) gives the following broad survey of ^{239}Pu activities in tissues of grazing cattle:

- from minimum detectable to 5 pCi/kg—kidneys, muscle, blood, whole fetus;
- from 1 to 20 pCi/kg—bone, liver, and gonads;
- from 10 to 100 pCi/kg—lungs;
- from 100 to 500 pCi/kg—tracheobronchial lymph nodes.

In a 1978 paper, Smith gives figures of <1,000 pCi/kg for rumen fluid, <5,000 pCi/kg for rumen vegetation, and <20,000 pCi/kg for skin and hair. Thus, the poor absorption of plutonium seen in laboratory experiments does not seem to have been changed much by the effects of environmental "weathering."^(b)

The finding of essentially equal amounts in bone, liver, and gonad was unexpected since laboratory work, quoted in earlier chapters, showed much less plutonium in gonad than in bone or liver. Smith points out the need for further follow-up. However, the NAEG is suffering from funding cuts and diversion of activity to the more general follow-up of fallout phenomena. This author has not found further confirmation of this finding.

(a) Formerly part of the Southwestern Radiological Health Laboratory.

(b) Note, however, that this work covers only a few years of such weathering.

Note that the units used above are picocuries per *kilogram* of tissue rather than per gram. Thus, the absolute amounts are not of immediate concern. Yet it must be remembered that these figures were from only a few years of grazing, and long-term accumulation or lack of it over many years of grazing in a contaminated area has not yet been ascertained.

Other work with large animals covered mechanistic items such as the metabolism of americium in dairy animals, solubility of actinides in ruminal gastrointestinal contents, and the resulting predicted tissue retention and milk secretion of field-ingested ^{241}Am , and other work linked to the laboratory studies described in chapter 13, except that they were done under the aegis of the NAEG.

G. Modeling

To further the goals of the NAEG, preliminary models were constructed of potential plutonium transport pathways from the environment to humans, partly to be sure the field work did not miss some important step. This work was spearheaded by W. E. Martin and S. G. Bloom at Battelle Columbus Laboratories (BCL). A version based on moderately early information from the NAEG studies was constructed to provide a basis for stating the probable rates of ingestion and inhalation of plutonium by a hypothetical Standard Man living in a plutonium-contaminated area like those at NTS. The parameters for metabolism once in the body were based on publications and recommendations of the International Commission on Radiological Protection (ICRP). This model was presented at the IAEA symposium on transuranic elements in the environment (Martin and Bloom 1976). Estimated doses due to inhalation and ingestion of ^{239}Pu , over a fifty-year period, were given as factors by which to multiply the average concentration of ^{239}Pu in the surface soil of the reference area. With this parameter expressed as picocuries per gram, the factors to translate to rem in fifty years turned out to be: 0.6 for thoracic lymph nodes, 0.025 for lung, 0.015 for bone, 0.01 for liver, 0.003 for kidney, 0.0007 for total body, 0.0003 for gastrointestinal tract.^(a) Note there is no figure for gonad and that the figure for gastrointestinal tract must involve much self-absorption. The authors show predicted dose commitments from ^{239}Pu and cumulative doses for fifty years in Standard Man living in an average NTS area. Lungs, bone, and liver approach 5×10^{-2} rem, thoracic lymph nodes approach 10^0 rem.^(b) They also calculate an MPC in soil on the order of 3 nCi ^{239}Pu /g soil, or about $270 \mu\text{Ci}/\text{m}^2$. Presumably, this equates to a lung dose rate of 1.5 rem/yr.

There were modifications in the model as work progressed (Martin and Bloom 1977) and an analysis of the effects of variations in source term and parameter values on the estimates of radiation dose to humans (Bloom and Martin 1978). As expected, fairly reasonable variations in such things as particle size and translocation class for inhaled material can make very large differences (several hundredfold) in the calculated dose. Thus, any single figure from models such as these cannot be used except for range-finding purposes. Naturally, quite conservative assumptions are usually made, so any final numbers quoted will usually be ultraconservative. We will return to some of these matters in connection with the work on setting soil standards to be discussed in chapter 15.

(a) Inhalation accounts for all of the dose predicted to thoracic lymph nodes and lungs, and for about 94% of the predicted dose to bone, liver, kidneys, and total body.

(b) Read from figure 5 of Martin and Bloom (1976).

H. Comment

The description above considers only a part of the work of the NAEG since it relates only to the actinides. Much was done also with fission products. A broader review can be seen from the report listing and contents in note 2.

As indicated earlier, the question was asked as to whether or not the work of NAEG on the safety-shot sites had not reached a logical termination point. Wallace and Romney (1978) could muster numerous cogent reasons for continuation, and this author agrees that many questions remain unanswered, especially when really long-term behavior is to be considered. However, the intense pressures of the weapons test fallout litigations (chapter 12) and other aspects of more dramatic and urgent proportions have siphoned off, at least temporarily, the will and resources to do what really should be done, even though we have the opportunity.

IV. Fission Product Field Releases

The possibility of release of fission products from a nuclear reactor stimulated much interest in gaining knowledge of the fractions of the total inventory that might be released, the chemical and physical form of the released materials, and their potential biological effects. We have already encountered many aspects of this problem. There were reasons to expect that many of them might differ appreciably from the fission products in fallout from weapons tests, especially worldwide fallout. Some of the potential contrasts were pointed out in earlier chapters (e.g., chapters 10, 11, 12). Yet, the newly developing nuclear industry could hardly be expected to do more than calculate. A staged melt-down of a complex and fully instrumented reactor could hardly be counted upon! Luckily, the same question arose in connection with plans for development of a nuclear powered aircraft. The U.S. Air Force went far enough with plans for such a development that they determined that some sort of field studies had to be done. These provided some of the types of data needed in the broader context.

Under the aegis of the Air Force Special Weapons Project, and as part of the "Aircraft Nuclear Propulsion Project," tests were planned with objectives broadly similar to those of the plutonium safety shots we have just reviewed. These were handled largely through the Air Research and Development Command at Kirtland Air Force Base at Albuquerque, New Mexico, and its contractors. There was particular collaboration from the General Electric Company for fuel element and hot-cell aspects; the University of Rochester for biological work; the Idaho Operations Office of the AEC for meteorology, health physics control and site survey, and ecological sampling; the Air Force Special Weapons Center for many logistic and specialized functions; and Convair-Fort Worth. It was determined that the most reasonably realistic surrogate for a potential accident involving an operating reactor propelling an aircraft was to melt down fuel elements and release their contained fission products under known conditions. Questions asked were: (1) release percentages, (2) particle size and size distribution, (3) atmospheric diffusion, (4) deposition on a variety of surfaces, and (5) uptake by living animals and plants, including possible biological effects.

The tests took place primarily at the AEC's National Reactor Testing Station near Idaho Falls, Idaho, but a few were conducted at the Dugway Proving Grounds in Utah. Convair-Fort Worth, the potential builder of a nuclear-powered aircraft, conducted the tests physically under direction of the Air

Force. The role of the University of Rochester was much as it was for the plutonium work. A fairly elaborate set of facilities for animals and biological work was built at Idaho Falls. All biological aspects, except certain ecological measurements, were the responsibility of the Rochester group. R. H. Wilson and R. G. Thomas were again key planners and operators for the biological program. They were joined by R. Lie and G. A. Smith from Rochester; B. B. Boecker, Rochester and later Air Force and Convair-Fort Worth; J. L. Terry from the Air Force; and L. J. Signeur who did behind-the-scenes work. Very satisfactory facilities were developed by modification of three standard Air Force truck trailers. Since these represent something of a climax in the development of such field facilities for biological work and they were very versatile, interior views of the laboratory and animal trailers are shown as figure 14.3A and B.^(a)

These tests were performed in the period July-October 1958. Unlike the work with plutonium, data for the total activity of fission products, the gamma spectra, and, to a degree, the apportionment of activity among the various elements could be determined relatively quickly. Indeed, the results of one test could be used to modify plans for subsequent tests. Also, unlike the work with plutonium, many variables could be introduced in the series and multiple tests accomplished. Besides meteorological conditions, the age of the fuel element, i.e., "green" or "aged" according to the time in the reactor, was a prime variable.

The exposures were carried out by fast melting of the fuel elements from a reactor in a special induction furnace at ground zero. The plume migrated down and across an array of air sampling instruments and animals (animals were not used in all tests). A plume of visible smoke was released immediately preceding and following the fission product release and the plume photographed by ground and aerial cameras. Also, a fluorescent nonradioactive tracer was released to simulate and measure the dispersal characteristics.

The reports of the biological aspects of this work are, primarily, three University of Rochester Atomic Energy Project reports entitled, respectively, *Field Studies of Fission Product Inhalation Parts I, II, and III* (Thomas et al. 1959; Wilson 1959; Thomas and Wilson 1959) and two large reports from the Air Force Special Weapons Center (ANP 1959, 1960). However, there were also Idaho Operations Office reports that gave full details of the physical phenomena (see, e.g., Bunch 1966).

These were relatively short-term experiments. The endpoint, both biologically and physically, was deposition. Few data extend beyond ten days after the release except for two dogs that were placed in metabolism cages and followed for fifty days, and there were some data on tissue content at 150 days or more. Major emphasis was placed on initial deposition and, thus, rapid retrieval of the animals from the field. Evidently the meteorological conditions were sufficiently reliable for the first Fission Product Field Release Test (FPFRT) that no special efforts were needed to provide for quick movement of the animals, as we saw in Operation Roller Coaster. Thus, the array was fixed within a sixty-degree sector, and experimental arcs were at 100, 200, 400, 800, 1,600, and 3,200 m and about 5 mi downwind of the release point. Animals were placed at the

(a) These trailers met their purposes so well that they served for several years as additional (and isolated) laboratory space behind the University of Rochester Atomic Energy Project.

FIGURE 14.3A. (Left) Interior view of trailer utilized for laboratory work, particularly radioactivity counting in the Fission Product Field Release Tests at the National Reactor Testing Station at Idaho Falls. (Courtesy of Wilson 1959.)

FIGURE 14.3B. (Right) Interior view, showing full length of animal trailer used in the Fission Product Field Release Tests at the National Reactor Testing Station. Beyond the dog cages at the far end is a furnace-air-conditioner, water heater and storage facilities. Normally cages for rats were mounted on the right wall. (The usual practice of not mixing species in animal care facilities was not employed because of the relatively short duration of the experiments.) (Courtesy of Wilson 1959.)

100-, 200-, 400- and 800-m stations and as close as possible to the air sampling instruments for those locations. The animals were white rats and mongrel dogs.^(a)

In subsequent operations, a track of perforated steel was laid down, and the animals were placed in wagons that could be moved by pulling on long ropes. This was indeed a prelude to the procedure used at Operation Roller Coaster.

Despite the predictions from experience, the first tests in the fission product release series were done without special precautions to minimize ingestion of materials deposited on the fur or around the noses of the animals.

In the trials with rabbits, reported in the Aircraft Nuclear Propulsion report (ANP 1959), scalp activity and lung activity were reported. In general, they correlated well with each other with distance from the shot release. In the early Rochester experiments, the animals were in open cages, and deposition in the gastrointestinal tract was unrealistically high. Alteration of the exposure cage design to minimize licking of the fur, anesthetizing the animals, and changing the methods of sacrifice brought the gastrointestinal-tract-to-lung ratios from more than thirty to one to less than one to one. However, care had to be exercised not to alter significantly the respiratory functions of the animals, and anesthesia was not used routinely. Changes in the contours of the exposure cages (primarily those for the rats), muzzling the dogs, and great care not to introduce artifacts at the time of collection were the most useful ways to avoid unwanted ingestion of the fission products. The nuances of these and other details of methodology are described by Thomas et al. (1959) and Wilson (1959).^(b)

It turned out that the "aged" fuel elements released an aerosol composed primarily of cesium. Indeed, about 83% of the premelt cesium was lost from the elements. Counting and dose calculations were relatively easy. The "green" fuel elements produced more of a mixture, but iodine predominated. In fact, the results were routinely reported in two parts, iodine and all other isotopes. The latter category had a half-life greater than thirty days. It was inferred that the iodine was largely in an uncombined form. Another difference between the two forms of elements was seen in the ratio of external contamination to lung. For the releases from green elements, this ratio (for iodine) was ten times that seen for cesium from the aged fuel elements. Thus, a difference in physico-chemical properties (solubility?) undoubtedly existed. For these reasons, the results for the two forms of elements were reported separately.

Deposition (median) in the lower respiratory tract of rats and dogs is summarized in the following data modified from Thomas et al. (1959):

aged elements:	green elements:
54 rats = 28%	116 rats = 33%
12 dogs = 24%	18 dogs = 35%

On this basis, the combined figure for deposition in rats was taken as 33% and for dogs 31%. What is not shown is the rather large range of variation of the figures. Nevertheless, the median figure for deposition in the lower respiratory

(a) Some of the ANP documents mention rabbits for some of the early tests. It is not clear who had responsibility for these, presumably not the University of Rochester. They appear to have been used only for measurements of external contamination. (Wilson [1984] suggests that this refers to the numerous indigenous jack rabbits.)

(b) The first test described by Thomas et al. (1959) released so little activity that no conclusions could be drawn.

tract was not seriously at odds with the usual figure, 25%, derived from the then-extant lung model (see chapter 16). Total deposition, i.e., deposition in (and on?) the whole animal, showed a median of 67% without much difference between aged or green fuel elements. For several reasons, the authors preferred to utilize a total deposition figure of 75% for hazard-evaluation purposes.

Tissues were analyzed in some instances for periods up to over 150 days after exposure. In addition to gastrointestinal tract (sometimes done in segments), lung, kidney, muscle, and blood were analyzed (the latter only when samples of 120 ml or more were available). The results are outlined below:

1. In the work with green fuel elements, stomach appeared to contain much more iodine than any other portion of the gastrointestinal tract or any other organ. The ratio of iodine to long-lived fission products was about three for kidney, lung, and small and large intestine, but it was about nine for stomach. Air-filter samples were like all organs except stomach. Thus, some selective accumulation in stomach must be considered.
2. Lung contents (total count) fell considerably less rapidly with time than did stomach, while kidney and lung were roughly comparable.
3. The time course and element ratios on the average air filter and in lung were roughly comparable.
4. Esophagus was high compared to lung or gastrointestinal tract after exposure to the aged fuel elements.
5. There was essentially no cesium in muscle, even from experiments with the aged-fuel-element release.
6. In general, radionuclides from the aged elements, e.g., cesium, were more slowly transported than those from the green elements, e.g., iodine.
7. Thyroid uptake was analyzed in some of the dogs, but only after *intravenous* injection.

The two dogs placed in metabolism cages for fifty days showed unexpectedly almost equal amounts of gross activity in urine and feces over the entire fifty-day period. This indicates the presence of insoluble radioactive material in the lung that was being gradually fed to the gastrointestinal tract by pulmonary clearance processes. Since the exposure came from what was considered a green fuel element, this implies that the mobile iodine was not the only element present.

The work at Dugway is described in the second Convair report (ANP 1960). The fallout patterns at Dugway are described therein for eleven releases using fuel elements of the type planned for the ANP reactor. Exposure of animals is indicated as having taken place, and the statement is made that the results would be reported by the University of Rochester. However, no such reports appeared. It is understood (personal communications from the Rochester group) that the biomedical data obtained could not be used.

The purpose of these tests was hazard evaluation. What was found that might modify analyses of hazard derived from laboratory experiments?

1. The age of the fuel elements makes an obvious difference in the elements of importance. This could have been determined from the laboratory work. However, the difference by a factor of ten in deposition velocity could not have been guessed.
2. The constancy of urinary to fecal excretion rates, seen in the metabolism dogs, was not expected.

3. Gross fallout measurements can give misleading results for estimation of body (i.e., lung) uptake. Individual elements must be considered in part.

Unfortunately, the number of animals in this work is small, and ranges of variation are large. A larger series might have made the conclusions more certain. Nevertheless, the work was a worthwhile check of field versus laboratory with, as in other cases, significant differences noted.

In a broader sense, it may be asked if these biomedical tests discouraged the further development of the nuclear-powered aircraft, particularly from the standpoint of potential environmental contamination. This seems unlikely. It is true that the longer-lived fission products could assume greater importance in the operation of such devices than in fallout from weapons tests. Yet, nothing in the reported results indicated the presence of problems so drastically different from the predictions that the project should be discontinued. It seems more likely that protection of the crews by shielding and by wide separation from the reactors presented more serious biomedical problems than those of environmental contamination. Nevertheless, the public reaction to a device that had to discharge some fission products to the atmosphere in normal operation and that could not be made heavy enough to contain, for certain, the enormous radioactive inventory in the event of an accident was likely to be quite negative. Very real advantages, even over and above the potential for very long flight times, had to present themselves.

In any event, the ANP project wound down, and there were no more biomedical tests. There were, however, related ones in the projects Kiwi, etc., as we reviewed in chapter 9 and will consider again briefly later in this chapter.

V. Project Plowshare

A. Development of the Plan

Project Plowshare was one of the most ambitious and extensive facets of the Atoms for Peace Program.^(a) It envisioned the use of nuclear explosives for relatively quick and inexpensive (in comparison to conventional means) digging of harbors; for releasing large stores of natural gas or petroleum trapped underground in impermeable strata; for transportation construction projects requiring the "moving of mountains"; waterways; even to the digging of a new canal from the Atlantic to the Pacific across the isthmus of Panama or adjacent thereto.^(b) It was a visionary project built around Isaiah's ancient prophecy, "and they shall beat their swords into plowshares."

Several books were written directly about the ideas of Project Plowshare. Two are cited for the reader's convenience: a semipopular description by Ralph Sanders, Washington, D.C., with a foreword by former AEC Commissioner Willard F. Libby (Sanders 1962), and a more technical treatise by Edward Teller and collaborators (Teller et al. 1968). There were, in addition, many special

(a) See especially chapter 20 and references given therein, as well as passing mentions in other chapters for description of the Atoms for Peace program and its origins.

(b) Other possible uses were in mining; the production of power by utilizing the long-lasting heat from a nuclear detonation in deep rock; the production of isotopes and of chemicals that could be extracted; and various scientific applications pertinent to neutron physics, geophysics, and space physics.

symposia on all aspects of the project. The Lawrence Livermore Laboratory of the AEC was founded largely because of the anticipated needs of Project Plowshare and was called upon for broadly based inspiration and guidance, as well as much labor. Consequently, a large number of Livermore reports pertain to the various aspects of the Plowshare Project. The AEC issued a booklet devoted to Plowshare in its information series, "Understanding the Atom" (Gerber, Hamburger, and Hull 1967).

These ideas were, of course, not a U.S. monopoly. Several countries showed interest and formulated plans. The Soviets not only had interest but are reported to have actually carried out some real projects, not just tests (Sanders 1962, references for chapter IX "The Soviet Stake"). There is no doubt that many of Russia's water problems might be susceptible to the enormous energies of nuclear explosives. Scheimer and Borg (1984) describe deep seismic sounding with nuclear explosives in the Soviet Union. Also, fairly recent newspaper stories (*San Diego Union*, Associated Press 1984) describe proposals to build a long-dreamed-of canal between the Indian and Pacific Oceans across Thailand's Kra Isthmus. Thus, the ideas are still viable.

B. Operations

A total of twenty-seven of the announced nuclear tests carried out by the United States (see chapter 12) were labeled as "Plowshare Events." These ranged from much less than a kiloton to over one hundred kilotons, largely underground or, at most, cratering events. Most were at NTS, but there were special events in Colorado and New Mexico. They occurred over the period December 1961 to May 1973. We will have reason to cite specifics concerning a few of them as we proceed.

Only a few of the twenty-seven shots had overt biomedical components. Most of this consisted of follow-up of fauna and flora in the craters produced or exposure of living organisms to the radioactive debris derived from the sites. One (the Sedan event) included placement of some animals by Placak's group for the PHS (Wilson 1984), but results seem not to be available. All had components of hazard evaluation, and for some this became a central feature.

A large effort was expended by the biomedical community in calculations of the potential doses to humans from radioactivity that might be released in large "geographical engineering" events. Principal among these were dose-estimation studies related to a possible Atlantic-Pacific Interoceanic Canal. While the overt cratering events were monitored by personnel from several laboratories, this computational work resided primarily at ORNL, Health Physics Division and Environmental Sciences Division, and BCL. Since this computational work had the most direct bearing on radionuclide problems, we will examine it first.

C. A New Interoceanic Canal—The Computational Approach

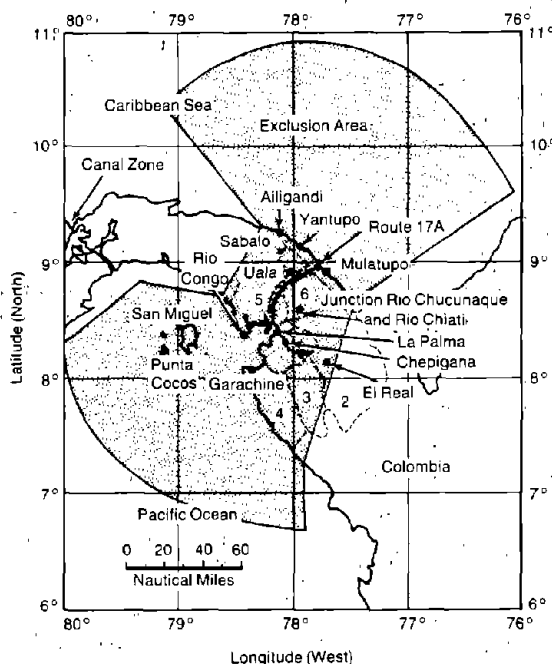

The idea of producing a sea-level canal by detonating rows of buried nuclear charges was consolidated into the Atlantic-Pacific Interoceanic Commission. With the internal dosimetry group at Oak Ridge already deeply involved in computer calculations for revisions of standards for exposure to radioisotopes being considered by bodies such as ICRP, the National Council on Radiation Protection and Measurements (NCRP), and the Medical Internal Radiation Dose [Committee of the Society for Nuclear Medicine] (MIRD) (see chapters 16

and 20); it was logical to ask them to expand further into population exposure standards. This resulted in a series of reports organized by Walter Snyder and carried on by his colleagues.

Tied closely to this work was that at BCL for provision of some of the potential source terms ($\mu\text{Ci}/\text{cm}^2$ of land surface and $\mu\text{Ci}/\text{day}$ intakes)^(a) and judgments to determine, on the basis of the ORNL and other analyses, if the nuclear excavation plan could be carried out safely. For this they used comparisons of the predicted doses to established radiation safety standards for populations.

Many potential routes for the canal were considered. The BCL personnel, the Puerto Rico Nuclear Center (particularly Frank Lowman), and PNL conducted onsite research in Panama and Colombia to check out the pros and cons of each route. By contrast, the ORNL calculations concentrated on only the two most promising routes: Route 17 through the Darien region of Panama and Route 25 across North-eastern Colombia. These are mapped in figure 14.4A and B. For each route, a combination of nuclear and high-explosive events was planned. This was taken into account in the dosage calculations.

FIGURE 14.4A. Map of Panama illustrating the Route 17 alignment, watersheds (numbered), and locations of towns and villages for estimates of external dose. (Redrawn from Kaye and Rohwer 1970.)

In-depth presentations of the enormous effort needed for the dosimetric calculations are given in three ORNL reports: Cowser et al. (1967); Turner, Kaye, and Rohwer (1968); and Kaye and Rohwer (1970). The objectives were estimation of potential radiation doses to humans, comparison of these to existing radiation protection guides, and recommendations to limit potential radiation doses to the lowest practicable levels. The three phases, which covered the periods July to December 1966, January 1967 to June 1968, and July 1968 to June 1970, respectively, are described as follows.

(a) Many additional input factors were worked out by ORNL.

FIGURE 14.4B. Map of Colombia illustrating the Route 25 alignment and watersheds (numbered). (Redrawn from Kaye and Rohwer 1970.)

Phase I—Quantification of transfer of radionuclides through critical exposure pathways, identification of critical radionuclides, criteria for evaluating radiological safety of nuclear excavation, and lists of radionuclides in order of external or internal exposure capabilities.

Phase II—Development of computer codes for estimating internal and external radiation doses under the conditions and modes of exposure expected to be important. Both the specific-activity and environmental-systems-analysis approaches were tested.

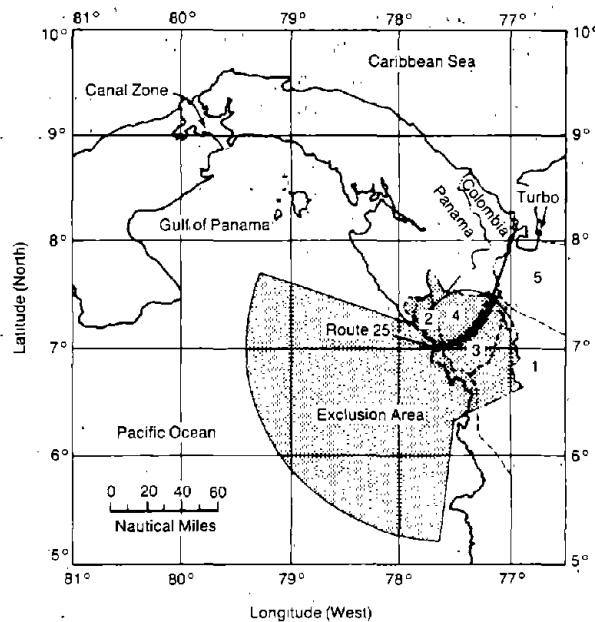

Phase III—Final estimates of potential doses, their assessment and formulation of recommendations.

We can summarize the results of each phase by reproducing the abstract from each document below:

Abstract of Phase I—This report presents information obtained by ORNL in Phase I of dose-estimation studies to evaluate the radiological-safety feasibility of excavating an Atlantic-Pacific interoceanic canal with nuclear explosives. The information includes (1) methods for estimating external and internal dose equivalents, for quantifying the transfer of radionuclides through critical exposure pathways, and for identifying the radionuclides likely to be critical; (2) criteria for evaluating the radiological safety of the operation; and (3) lists of radionuclides arranged according to the dose commitment that results from exposure to a unit quantity of each radionuclide. Equations to estimate external and internal radiation dose commitments were developed which account for production, venting, and movement of radionuclides in environmental exposure pathways. A compartment model for representing movement of radionuclides in the tropical environment was designed with coupled compartments having income and loss fluxes controlling the inventory of radionuclides which may have inputs to man. The specific activity concept for estimating the allowable radionuclide concentrations in the environment was evaluated in a way that reveals its limitations, considering the time-dependent relative importance of radioactive half-life, biological half-time, and biological growth.

Criteria for evaluating radiological safety were developed from the recommendations of recognized authorities which might reasonably apply in an operation of this magnitude, taking account of the principle of balancing the possible benefits against the potential risks.

(Cowser et al. 1967)

Abstract of Phase II—EXREM is a computer code to estimate the dose equivalent rate and the total dose equivalent from both beta and gamma radiation resulting from submersion in contaminated water, submersion in contaminated air, and exposure to a contaminated surface. There can be more than one environmental release, and exposure can begin at any time after the first release. INREM is a computer code to estimate the cumulative dose equivalent to body organs resulting from a continuous intake. The organ parameters are dependent on the age of the individual, and the intake is a function of post-detonation time and the individual's age.

Although the codes were specifically written to estimate doses to populations from construction of a sea-level canal, they may be useful in other dose-estimation studies involving releases of radioactive materials to the environment. (Turner, Kaye, and Rohwer 1968)

Abstract of Phase III—This document is the final report covering contributions of the Health Physics Division of Oak Ridge National Laboratory (ORNL) to the Bioenvironmental Radiological Safety-Feasibility Study of a sea-level canal excavated with nuclear explosives. Potential doses to indigenous populations along Route 17 in eastern Panama and Route 25 in northwestern Colombia were estimated for a combination of hypothetical exposures to radiation. The studies attempted to determine when it might be appropriate for the evacuated populations to reenter areas adjacent to the two routes. The only modes of exposure considered were external exposure to a contaminated land surface and internal exposure from the ingestion of four types of contaminated foods and beverages. Parameters in the internal dose models were adjusted to differentiate five age groups within each of four indigenous populations and nine reference organs. These populations were further differentiated on the basis of diet and estimates of time- and age-dependent concentrations of radioactivity in dietary items. Intake functions (μCi ingested per day) for internal dose estimates were average values for watersheds with the highest initial areal concentration of fallout along each route, whereas external doses were computed for 13 locations (towns and villages) in watersheds of the exclusion zone of Route 17 only. Estimates of potential external doses were based on 170 radionuclides; only 31 radionuclides were considered in detail for the estimation of potential internal doses, with an approximate estimate of total dose from the radionuclides not included in the list of 31.

Estimates of potential total doses (internal dose from ingestion + external dose from land surface) were assessed in terms of radiation safety criteria recommended for members of the public by recognized authorities. The basic criteria were: annual dose limit for the total body of 0.17 rem/year and a genetic dose limit of 5 rem/30 years. Assessments based on somatic doses suggest reentry may be appropriate 8 to 10 years after the last detonation. Children less than 5 years of age at the time of reentry may be the critical age group among the age groups for which doses were estimated. Within this age group, no single ethnic group emerged as the most critical. Assessments based on genetic dose appear to be less limiting, suggesting that reentry may be possible within months following the last detonation. These assessments are based on comparisons with the total doses allowed under the radiation safety criteria. In actual practice, however, some apportionment of these criteria might be likely. Such an apportionment should be undertaken by the countries involved (Panama and Colombia). (Kaye and Rohwer 1970)

These abstracts, particularly the one from the Phase III report, give figures for safe re-entry, as we see, from eight to ten years, based on somatic dose. These would create the impression that some final conclusions had been reached and that the projections were unlikely to be acceptable. Any project that would require such long waiting periods for return to full-time habitation

and temporary domicile elsewhere under conditions that would be far from ideal was hardly one to gain much support, particularly for populations of countries with a relatively small stake in the project. This would hold even if the exclusion area gradually narrowed down to a mile or two from the excavation site. (The cratering shots at NTS showed that most of the radioactivity was in the material actually thrown out of the crater and did not extend very far except for the initial cloud.)

Reading further into the detailed discussion, we find that the authors of the Oak Ridge reports concluded that they could not provide a definitive assessment of radiological safety with the information at hand. Three potentially important routes of exposure were not included in the studies: submersion in air, submersion in water, and inhalation.^(a) Furthermore, the parameters for humans and the environment were not only numerous but had to be based upon data using Standard Man^(b) and environmental practices in North America and Europe, not the ethnic groups or agricultural practices of Central America. The authors recommended stable element analyses of total diet and total excreta in the areas of interest for the canal; measurements of organ weights, dimensions and stable element contents using cadavers; direct determination of intercompartmental transfer functions in the tropical ecosystems involved; etc.

It is hard for this author to see how gathering such information, and it would require a large research effort, could alter the conclusions sufficiently to make the project look really attractive. Yet, he must agree with the authors when they say, "For a project of this magnitude and potential impact, educated guesses or unfounded assumptions are not a satisfactory substitute for real data, especially when it is technically and economically feasible to procure the necessary data on which a realistic assessment could be made" (Kaye and Rohwer 1970, p. 98).

On the other hand, the study appears not to have uncovered radiological problems that could not be managed by "adequate planning and reasonable precautions," some of them quite demanding, even drastic, except for one unknown. The large amounts of radioactivity trapped at or below the bottom of the proposed canal could not be counted upon to remain there indefinitely. Yet, models for the behavior of this component seemed especially difficult to construct.

Despite the fact that the answers could hardly be expected to generate unbridled enthusiasm for the canal project, the work served many useful purposes. It developed an approach to evaluation of environmental and population exposures that had much greater flexibility and versatility than the old system of MPCs. It went far along the path of identifying and isolating critical processes, critical populations, and critical radionuclides. Its usefulness went far beyond the calculation of potential radiological safety in Project Plowshare. Glimpses of this can be seen in the open literature publication by Kaye et al. (1969).

For example, the work led to the development of a generalized exposure index system called CUEX (Cumulative Exposure Index) and fed much information and technique into the ongoing work of ICRP, NCRP, the Nuclear Regulatory Commission, and the federal establishment in general. These will be

(a) The open literature publication by Kaye et al. 1969 appears to include these:

(b) For example, the internal dose parameters used for the INREM code were Standard Man values or modifications thereof.

discussed briefly in chapter 16. The CUMEX program will be described in chapter 15, since it pertains more to environmental transport problems, in general, than to Project Plowshare alone.

The computational approach in the enormous effort described above was largely a systems-analysis approach. In earlier discussions, we mentioned that a specific-activity approach had been applied to environmental dose assessments. The Oak Ridge people took pains to present a formal discussion of this approach, particularly since it was suggested by the National Academy of Sciences-National Research Council committee on Oceanography and Fisheries, as described in chapter 11.^(a) Kaye and Nelson presented a concise analysis of the specific-activity concept as related to environmental concentrations of radionuclides, with the conclusion that bioengineering of the proposed Inter-oceanic Canal could be approached through the specific-activity method as well as others' (Kaye and Nelson 1968). The major problem with the approach is incomplete mixing of the stable and radioactive isotopes and potential differing biological availability of the stable and radioactive components—not minor problems.

These computations for Project Plowshare obviously contributed considerably to the progress of internal emitter dosimetry. When one considers the hundreds of nuclides examined, their ranking according to their importance in each of several intake patterns, and the exhaustive analyses of the environmental transfer processes (to be discussed in chapter 15), this conclusion is amply supported. Nevertheless, attention gradually moved toward other applications. First we must look at the types of biomedical work done in connection with the cratering tests.

D. The Cratering Events

Of the twenty-seven special nuclear explosions labeled as Plowshare shots, all but five took place in underground shafts or tunnels. These five exceptions took place at NTS. One of the most spectacular, as well as one of the earlier shots, was the "Sedan" shot. A 104-kt device was exploded 635 ft below the surface on July 6, 1962. (This had been preceded by several smaller cratering experiments. One of the objectives was to test the validity of the scaling laws developed.) The shot excavated a crater 1,200 ft in diameter, and 320 ft deep, and it moved a volume of 6.5 million cubic yards of desert alluvium. A picture of this awesome cavity is shown as figure 14.5.

Most of the radioactivity was deposited nearby, but appreciable amounts of fallout with external dosage of over 0.5 R infinite dose were carried for up to one hundred miles. A diagram of the fallout pattern is seen in figure 14.6.

Note that the contours given are for the infinite dose and also that the technology between 1962 and 1965 improved considerably and was postulated to improve still further with future developments. However, we have heard little more about these.

Other pertinent cratering events were Cabriole, Buggy, and Schooner. These had lower yields, viz., 2.3 kt, 5.4 kt, and 30 kt, respectively. The last announced cratering event took place in December 1968.

(a) Remember, too, that the concept was applied by the Oak Ridge group to clams and clam shells and ^{90}Sr in the Tennessee River system.

FIGURE 14.5. The 100-kiloton Sedan event formed the largest excavation ever produced by a single manmade explosion. Note the size of automobiles and structures near the crater's rim. (Courtesy of Gerber, Hamburger, and Hull 1967, p. 34.)

FIGURE 14.6. The radioactivity escaping from a nuclear excavation depends both on the total amount produced by the explosion and the fraction that escapes into the atmosphere. The diagram on the left shows the pattern of the fallout that was observed in 1962 from the 100-kiloton Sedan experiment. The center pattern indicates the fallout that might have been expected if Sedan had been conducted with 1965 technology. Explosives development and improvements in emplacement techniques are expected to reduce the radioactivity released from nuclear excavations to that shown in the right-hand drawing. The decrease from the left-hand to the

right-hand pattern is about a hundredfold. The amount of radioactivity released is relatively independent of the size of the explosion. These fallout patterns, shown in terms of infinite dose, indicate the dose of external gamma radiation that a person living outdoors for a lifetime might receive at various distances from the excavation. For comparison, the average external gamma dose a person in the United States receives from natural sources of radiation is about 0.1 roentgen (R) per year. (Redrawn from Gerber, Hamburger, and Hull 1967, p. 19.)

Biomedical work in general around these cratering events consisted of, in addition to the monitoring and dosage estimations, examination of flora and fauna from within and around the sites. This was aimed primarily at identifying the radionuclides present and gauging their mobility in the biosphere. Particular interest centered on the radionuclide species induced by the large neutron fluxes. The work was done largely by the groups at LLL and UCLA. Some of the work was in the field, some of it brought the contaminated soil to the laboratory for work under more controlled conditions. Typical examples are: (1) for Project Sedan, the neutron activation products in plants and soils (Romney and Rhoads 1966)^(a) and concentrations of radionuclides in plants grown in ejecta from Sedan (Romney et al. 1967 and a report on beagles at Project Sedan [Fountain 1963]); (2) availability to aquatic animals of short-lived radionuclides from the Cabriole event (Harrison 1973); and (3) availability of radionuclides from the Buggy cratering event to the peccary pig, and to the domestic pig from Project Schooner (Chertok and Lake 1971a,b).^(b)

There was also a series of UCLA reports and reports in the Plowshare series concerning additional biomedical studies of the Sedan test. These considered effects on close-in vegetation, direct effects (Martin 1963), food-chain relationships of radioiodine (Turner and Martin 1964), and of radiostrontium (Martin and Turner 1965); also a "final" report concerning movement of radionuclides in soil (Essington, Nishita, and Steen undated). There was also work on the population of lizards at Project Sedan (Turner 1963). All of this work is replete with modeling and undoubtedly contributed to the input data utilized by BCL in the computations described in section C.

The Sedan products were found from both laboratory and field experiments to contain so much tungsten that the investigators concluded it had been incorporated in the device. There were considerable differences in the way different nuclides were handled. Some concentrated more in leaves than stems, some vice versa. Plant uptake was influenced quite considerably by the type of soil, as we saw in chapter 13.

The work with the Cabriole soil was done in the laboratory by circulating aquarium water through a column containing the ejected soil. The main potential contributors to humans from either freshwater or marine animals were ^{131}I , ^{140}Ba / ^{140}La , and ^{185}W .^(c)

The work with the peccary pig was also in the laboratory. Two pigs were given single oral doses of the fallout from Project Buggy, the fallout having been collected on a tray about 1,000 ft from the detonation. Urinary and fecal excretion were measured and gut absorption calculated. Only iodine was absorbed to any significant extent. Again, some unfamiliar radioisotopes appeared in the cadre.

There was also work concerning the distribution of radionuclides in ground water after underground explosions like those in the Plowshare series (Stead 1964).

It was clear from all of this that the inventory of radioisotopes could vary with the shot; partly because of the circumstances of the event and partly because weapons designers manipulated the contents of the devices to meet their own purposes. Fortunately, these did not make serious problems for the biomedical

(a) This followed an earlier report on the fission products found in Project Sedan soil.

(b) The first work was one among many from UCLA; the others were part of the work at LLL.

(c) Note that this line-up is somewhat different from that seen with fallout from weapons.

evaluations, although there is no doubt that the order of elements might be changed in computations such as those described in section C. Also, fortunately, the key "bad actors" seemed to remain pretty much the same, despite the differences in details of the events.

E. Gas Stimulation Experiments

One of the more carefully tested ideas in the Plowshare domain was the use of nuclear explosives to release natural gas from impermeable strata. It has been estimated that trillions of cubic feet of natural gas are impounded in the earth below and within strata that are impermeable to either gas or oil. As described in the general references (Sanders 1962; Teller et al. 1968), nuclear explosives seemed especially adapted to tapping some of these resources. The enormous heat and fracturing of large areas of rock were considered strong plus values over the release by chemical explosives, a process already tried and known to be successful, but on too small a scale. However, the gas so stimulated could not help but contain measurable, perhaps even hazardous, quantities of radioactivity. Thus, tests done to see if stimulation could be brought about included fairly elaborate procedures to check total radioactivity released, to identify the radionuclides likely to be of the greatest importance, and to make judgments concerning the possible hazards of use of such gas under commercial and domestic conditions. One of the tests even resulted in litigation and a court judgment on the hazards.

There were three fracturing experiments,^(a) all officially part of Project Plowshare and each a joint U.S. government-industry cooperative venture. Project Gasbuggy involved a 29-kt device exploded in strata near Farmington, New Mexico; it took place in 1967. Project Rulison involved a 40-kt underground (shaft) detonation near Rifle, Colorado, in September 1969. The final test, Project Rio Blanco, took place near Meeker, Colorado, in May 1973. This involved three separate 30-kt devices in the same borehole at depths of 1,779; 1,899; and 2,039 m below the surface. Each site was, of course, chosen to be suitably isolated yet approachable and in formations where gas was expected to be available for stimulation. The stimulation was successful in each case.

It was decided from the outset that none of the released gas would be put into commercial or domestic mains. Yet, the necessary biomedical and other information could not be obtained without burning the gas in some way. Also, the gas could not be released safely to the environment without burning. Thus, it was decided to engage in periodic flaring of the effluent. The meteorologists and aerosol scientists found much to measure during these flaring events. We will sample the biomedical work.

In connection with Project Gasbuggy, investigators from the EPA laboratories in Las Vegas (Mason et al. 1971) soon identified the primary radioactive component of the gas, from the standpoint of hazard, to be tritium. They measured its uptake, largely as tritium water, by desert vegetation. This was done by extracting and measuring the tritiated water from vegetation samples. The amounts ranged from well below to factors of ten or more above background,^(b)

(a) So called because the prime interest was fracturing of the impermeable rock strata.

(b) For technical reasons, background was not determined for plants on the site prior to flaring. Instead, a background level for tritium in vegetation was estimated from samples collected independently over portions of Arizona, Colorado, and New Mexico.

depending upon location with relation to the stack and micrometeorology of each sampling location. The primary conclusions related to technique and the testing of various equations for movement of small air masses over rugged terrain, but they also addressed the best way to express tritium concentration in such samples. It was decided that for some purposes specific activity was best, for others the concentration on the basis of dry weight was best. It was recommended that both be used.

A thorough analysis of radioecological processes at Project Rulison was presented by the LLL people at the Third National Symposium on Radioecology (Anspaugh, Koranda, and Robison 1971). Their findings, which incidentally mentioned that successful development of the nuclear gas stimulation technology could double the proven recoverable natural gas resources in the United States, were a clear example of the need for such tests. Concentrating on releases of tritium, as THO (or HTO), they found that the environmental residence time of HTO is at least an order of magnitude shorter than was projected by computations.^(a) This in turn invalidated the deposition-velocity approach for the calculation of doses due to food-chain contamination.

On the basis of the actual data, the LLL investigators developed new models to predict the dose to humans via forage-cow-milk, forage-cattle-beef, vegetation, and inhalation pathways for HTO, and immersion dose for ^{85}Kr . All of these were based on flaring of the gas according to predetermined schedules. An upper limit of 3×10^{-6} rem to the Rulison residents was determined, which is between three and four orders of magnitude lower than preflaring estimates by several organizations, including LLL itself (Robison and Anspaugh 1969).

An attempt was made to verify the model by environmental samples, even though most of them had to be expected to be below detection limits. The EPA collected twenty urine samples from local residents, seven animal, eight milk, and fourteen vegetation samples (Gotchy 1971; Carter 1971). Only four samples, all of them vegetation, were above background (about 1 pCi/ml). Anspaugh also collected vegetation and milk, but no samples contained tritium levels above background.

Anspaugh et al. extrapolated the Rulison calculations to large-scale uses. If natural gas with 1 pCi of tritium/cm³ of gas were used to replace natural gas for heating and cooking in the Los Angeles or San Francisco Bay area, the dose to users by inhalation and absorption would be about 5×10^{-3} rem/yr. It would be 2.1×10^{-4} rem/yr to infants by all pathways if the stimulated natural gas were used to produce electricity instead of directly for heating or cooking.

Somewhat later, the Oak Ridge group (Health Physics and Environmental Sciences Divisions) evaluated all three gas stimulation experiments. Although the inventory contained ^3H , ^{14}C , ^{37}Ar , ^{39}Ar , ^{85}Kr , and ^{203}Hg ,^(b) it was computed (Rohwer et al. 1973) that tritium contributed 60% of the somatic dose and 93% of the genetic dose, while ^{85}Kr contributed 39% and 6% of these doses, respectively. They calculated doses to individuals resulting from combustion of the gas in unvented home appliances as less than 20 mrem/yr. Since most U.S. cities and states require venting of gas appliances, except cooking stoves, this figure is clearly a maximum. If the nuclear-stimulated gas were used for providing electricity, the maximum individual dose was calculated to be 0.006 mrem/yr or,

(a) Laboratory work at Livermore confirmed this finding.

(b) From neutron activation of stable mercury in the rocks.

using a particular station in and the demography of the Denver area, 0.32 man-rem. By contrast, in using the gas directly in the home, making many assumptions about the proportion used for various purposes, the population dose came to about 110 man-rem, or nearly 350 times the population doses accumulated by using the same amount of gas to generate electricity.

Despite this apparently large factor between modes of use, it is clear that the population doses to be expected if natural gas like that from Rulison were used commercially would be, in either situation, very small. Doses from radon and its daughters in indoor air are notably higher (chapter 3, NCRP 1984). Whether or not stimulated natural gas could actually be obtained at average or maximum levels like $1 \text{ pCi } ^3\text{H}/\text{cm}^3$ is not easy to guess. Scaling factors are currently quite crude, and the biomedical and seismic effects of much larger stimulation experiments cannot be judged on a priori grounds. Thus, we must withhold judgment regarding the actual doses that might ensue.

It was the Rulison experiment that became grounds for litigation. It was contended that current radiation protection standards were insufficiently conservative and would not protect life, health, and property if the stimulated gas were released or flared as per plan. A nonjury trial was held in Federal District Court in Denver and heard by Judge Alfred A. Arraj. The details are available in the public record, including the newsletter of the Health Physics Society in 1970. The ruling, which found there was no unacceptable hazard, is an excellent summary of radiation protection philosophy and ideas as they stood at the time. It can only be surmised what the ruling in a similar case might be at present.

Despite the evidences that doses would be low from use of stimulated natural gas, this feature of Plowshare died too. Whether or not the biomedical aspects were a central cause cannot be stated. There were many other factors such as costs, lessening of demand for new domestic supplies of gas, and general public suspicion of anything nuclear.

F. Alaskan Operations

Edward Teller, who can be regarded as at least a patron, if not the father, of many aspects of Plowshare, fostered elaborate plans for a "harbor-digging" (actually a cratering test) along the coast of Alaska. To prepare for such an event, or events, an extensive ecological program was undertaken. This, plus the other planning and feasibility studies, was called "Project Chariot." The biomedical aspects were contained in a large book entitled, *Environment of the Cape Thompson Region, Alaska* (Wilimovsky and Wolfe 1966). A quotation from the foreword for this book gives the purposes and an overview of what was done.

After the consideration of a number of possible locations for the project, a site at the mouth of Ogotoruk Creek near Cape Thompson on the northwestern coast of Alaska was selected for detailed study. Because the project site was in an environment for which there was no prior nuclear test experience and little scientific knowledge of the environment, bioenvironmental investigations in addition to the usual public-safety program were approved to allow adequate assessment of the effect of the proposed project and to assure that it could be conducted safely.

Accordingly, the San Francisco Operations Office, AEC, formed a committee, chaired by a member of the Division of Biology and Medicine, AEC, to develop and recommend a program of environmental studies for Project Chariot. Members of the Committee were selected from a variety of scientific disciplines on the basis of their experience in arctic research or in the effects of nuclear explosions.

In carrying out its assignments, the Committee set the following objectives:

1. To become sufficiently familiar with arctic ecological systems in the project area to permit: (a) estimates of the biological cost of the excavation operation and (b) judgements as to whether or not there would be effects that could result in widespread damage or major disruption of ecological systems.
2. To become sufficiently familiar with the biological and physical environments that the findings could be used as base lines in studies to be conducted in post-excavation time.
3. To determine radiation levels and the distribution of the radioisotopes in the biota and physical environment in pre- and postdetonation time.
4. To conduct all studies in such a manner that the results would constitute a significant contribution to scientific knowledge.

Implementing these objectives, the Committee initiated more than forty separate investigations, conducted primarily during the period 1959-1961. These activities were performed by university, private, and governmental research organizations under contract to, or agreement with, the Atomic Energy Commission.

Since by 1962 much of the desired nuclear-excavation engineering data originally planned to be obtained in Chariot had become available or would be available from other experiments being planned, the Atomic Energy Commission announced that it had decided to defer further consideration of the proposed Chariot experiment. Accordingly, Project Chariot was suspended and the bioenvironmental studies were concluded.

The scientific studies of the Environmental Program, although naturally lacking any postdetonation studies, have been compiled in this volume to present the scientific community with an integrated reference collection of technical papers accruing from the investigations. The breadth of environmental features studied at the Chariot site and in the adjoining area, and their interrelations, will be apparent to the reader of this book.

(Wilimovsky and Wolfe 1966)

The Committee was chaired by John N. Wolfe of the AEC, while Allyn F. Seymour, University of Washington, was deputy chairman.

Major research groups who participated in the Project Chariot field studies included Hanford; University of Washington; U.S. Geological Survey, Menlo Park, California, Denver, Colorado, and Silver Springs, Maryland; U.S. Weather Bureau Research Station, Las Vegas, Nevada; Marine Mammal Biology Laboratory; Bureau of Commercial Fisheries, Seattle, Washington; Arctic Health Research Center; PHS, Anchorage, Alaska; University of Alaska; Scripps Institution of Oceanography; McGill University, Montreal, Quebec; and the University of British Columbia.

These studies were hardly what was in mind when the original plans were laid to carry out a full harbor-digging operation under Project Plowshare. On the other hand, the basic information obtained regarding the undisturbed arctic environment was unique and voluminous and is contained in the Cape Thompson compendium. There was further activity in Alaska, but it was not part of Project Plowshare. It came somewhat later and is described in section VI C of this chapter.

VI. Related Projects and Events

In chapter 9, we had occasion to report the exhortations of Dr. William E. Lotz, who was responsible for management of much of the inhalation toxicology work in the Division of Biology and Medicine at AEC Headquarters, to the internal emitter workers to apply their energies to certain practical problems

that were requiring urgent attention. These problems had peculiar code names, not all acronyms, like Kiwi, ROVER, NERVA, and SNAP. They could hardly be regarded as Plowshare events *per se* since some had military overtones, but they resembled those we have been reviewing and belong in this discussion of "special events."

It was anticipated that the primary hazards from these would be inhalation. Hence, they were urged on at a symposium on inhalation toxicology. It has turned out that the problems were not exclusively inhalation, and what detail we can present is appropriate here rather than in chapter 9. The devices included the Nuclear Engine for Rocket Vehicle Application (NERVA); the experimental reactor for rocket propulsion that was code-named "Kiwi" after the flightless New Zealand bird, since there was no plan whatsoever that the device would leave the stationary pad; nuclear rocket propulsion, in general, "ROVER"; and, finally, the large project using radioisotopes for generation of heat that could be converted into electricity. The latter devices were used on space probes and in remote areas of the earth under the acronym "SNAP" (for Systems for Nuclear Auxiliary Power). As discussed earlier, this was the only project of those named that was technically highly successful. The others seem, in retrospect, like over-enthusiastic plans for use of nuclear energy and not always well planned. Nevertheless, they consumed several millions of dollars and required much work from the biomedical community.

A retrospective view of these enterprises and present developments was given by Broad (1982) in a general discussion of nuclear power in space, which included a second generation of SNAP, the Radioisotope Thermoelectric Generator (RTG).^(a)

A. Nuclear Rockets

The possibility of developing nuclear propelled rockets was a joint project of AEC and the National Aeronautics and Space Administration. Los Alamos played a key role in developing the technology.

The reactor designed to someday power a nuclear rocket was static tested under immobile conditions, and hence flightless like its New Zealand namesake, in a remote area of NTS. There was the usual cooperation from PHS and the Weather Bureau in Las Vegas. The tests began during early summer of 1959 and continued for a considerable period. A vigorous radiological safety program was conducted along with the engineering development.

A report on Kiwi, complete enough for our purposes, was presented by Langham (1962). He reviews the results of three tests of prototype reactors. Studies were made of the neutron and gamma-ray source strengths during operation and of fission product releases. The reactors would deliver lethal doses of neutron and gamma radiation in less than 0.1 sec at a distance of twenty feet during full operation. Thus, no one was expected to be close to these devices during the tests. At ten miles, the dose was essentially zero. Even at two miles it was only about 0.3 rad.

(a) Broad refers to SNAP as "Space Nuclear Auxiliary Power" and states that it began in 1955 and included solid-core fission reactors for the production of electricity in space. It is this author's impression that the major effort in SNAP involved only radioisotope heat sources rather than reactors.

The radiation doses from accumulated fission products attracted the most attention. The Los Alamos biomedical study (Langham 1962) presents total doses as a function of distance due to cloud passage after a maximum credible accident at the end of full-scale operation on the pad. These were 2.9 rad at one mile, 1.3 rad at three miles, and 140 mrad at ten miles, but were extremely high close in. He also presents anticipated dose rates as a function of time after impact if a 1,000-MW reactor should land intact or be destroyed and the fission products spread uniformly over either 0.1 or 1.0 mi², or land in shallow water, or enter the atmosphere from orbit. Various times of operation were incorporated into the estimates. Finally, he compares the contribution of fission products from projected nuclear rocket operations to then-extant tropospheric and stratospheric fallout. There was no doubt from all of this that evaluation of the initial dose rate was essential to management of any incidents, since the time of operation, time after shutdown, etc., could make enormous differences.

More actual data on fission-product production and fallout were contained in an oral presentation by Isaac Van der Hoven of the U.S. Weather Bureau in Las Vegas at the 187th National Meeting of the American Meteorological Society at Eugene, Oregon (Van der Hoven 1960). The presentation concerned mostly a fallout model but also contained the data. Among other things, Van der Hoven showed that the distribution of radioactivity was not uniform among particle sizes. The 5- to 20- μ range contained about 39% of the beta and 38% of the gamma activity, and the particles above 44 μ contained 34% and 38%, respectively.^(a) The closest third was the range 20 μ to 44 μ . Particles below 5 μ carried much less of the activity. The decay rates of these fission products were as $t^{-1.39}$ from H + 50 to H + 145 hr, and as $t^{-1.04}$ from H + 145 to H + 280 hr. The total integrated fallout from the Kiwi-A test, to which all of this refers, was 0.011 MCi. For comparison, a typical detonation in the Hardtack Phase II series (Otero) under way at the time, produced about 0.55 MCi of fission products.

The general conclusions from this work were that the release of fission products can be far from minuscule and is something to be reckoned with. Both site of firing and the trajectory would have to be carefully chosen. It does appear that a significant fraction of the fission products from the prototype device might be above respirable size. Thus, inhalation hazards would not be of exclusive concern.

The fuel elements of the experimental reactor for ROVER contained about 10^{12} particles of uranium-235 carbide ($^{235}\text{UC}_2$) of about 100- to 200- μm diameter (Dean and Langham 1969). The particles would have undergone as many as 10^{13} fissions and have dose rates of 10^8 rad per hour at thirty minutes after reactor shutdown. Even one of these on the skin could be of concern.^(b) Thus, the hazard analysis needed consideration of the effects in both lung and skin of some very hot particles.

The paper by Dean and Langham is an excellent discussion of the possible tumorigenicity of various sizes and activities of particles. It included some experimental work with three monkeys and two men. The calculated results are shown in table 14.2. The conclusion was that five hundred biological sites would have to be exposed to the highest dose to be certain of producing a tumor.

(a) Remember the 44- μ rule developed by UCLA for NTS weapons fallout?

(b) Such particles could also be of significance in the upper respiratory tract according to work of Sanders at PNL.

TABLE 14.2. Exposure of Human Skin to Fissioned $^{235}\text{UC}_2$ Microspheres

Fissioned $^{235}\text{UC}_2$ Sphere	Dia. (μ)	Exposure Time (hr)	Dose at Basal Layer (rad)	Tumor Probability
1	174	1.6	14,200	8.1×10^{-4}
2	159	5.3	40,000	8.1×10^{-3}
3	140	6.1	54,000	2.0×10^{-3}

Source: Modified from Dean and Langham 1969. Note: Calculations based on model developed in the cited paper and the noted effects of the actual skin exposures. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1969.

Again, it is difficult to say that biomedical problems led the way to the demise of this project. Clearly they were not negligible. This author remembers being present at a meeting where it was stated firmly that a nuclear rocket for propulsion of a space vehicle could never be used in the launch phase or in earth's lower atmosphere. That would have to be done with conventional chemical propellants with the nuclear rocket taking over to help move the vehicle into higher orbits or into the solar system or beyond. Even though the project seems dead for now, the presence of these biomedical evaluations may be of use should it be resurrected or other problems arise with similar characteristics.

B. SNAP

As indicated earlier, SNAP is the only program of this group that went through development and became operational. Today there are many thermoelectric generators on satellites now in orbit or in space trajectories, on the moon, and in remote areas of the world, all obtaining the heat for their electrical power from the presence of large quantities of radioisotopes. A summary of the SNAP devices launched through the mid-1970s is given in table 14.3.

Note that these devices contain primarily ^{238}Pu with small (relatively) quantities of ^{239}Pu . Almost a million curies of ^{238}Pu have been incorporated in these devices. The first such source contained ^{210}Po and was demonstrated personally by President Eisenhower by having it light a small electric bulb on his desk. Later, ^{90}Sr was used, but the alpha emitters have the advantage of requiring less shielding. Lotz (1964) lists eighteen materials used or proposed for SNAP devices. However, the choices gradually narrowed down, and plutonium became, and is, the most common material used. There is no question but the very considerable increase in demand for ^{238}Pu resulting from this choice led to much of the experimental work with this isotope that we have already reviewed.

There were two major safety concerns with these devices: mishaps during the early phases of launch, which would bring the device violently back to earth; and uncontrolled orbital decay and atmospheric re-entry. The engineers took care of the first problem by exceedingly sturdy construction that withstood the most severe tests without breaching the source container. By contrast, it was determined, for the early generation of devices, that controlled re-entry from orbit could not be guaranteed and that the design should assure complete burn up of the fuel core in the upper atmosphere.

TABLE 14.3. Summary of Launched Space Nuclear Power Systems

Mission	Launch Date	Fuel Form	Activity, Ci		Disposition
			²³⁸ Pu	²³⁹ Pu	
Transit 4-A	6/61	Plutonium metal	1,800	1.3	In >1000-yr earth orbit

Source: Reset from Dobry 1980.

In later generation devices, the engineering was able to meet an intact re-entry as well as intact impact philosophy (Dobry 1980).

These devices were not put into orbit overnight. There was a SNAP Hazards Safety Committee of the AEC, which met often and weighed the alternatives diligently. Health hazards played an important role. Many meetings were held

under the aegis of the Division of Biology and Medicine (DBM). The results of two of these were kindly made available by Dr. H. D. Bruner, who had much of the responsibility in Headquarters.^(a) The members were, in addition to Dr. Bruner, Roy Albert (New York University); William Bair (PNL); Birney Fish (ORNL); Wright Langham (Los Alamos Scientific Laboratory [LASL]); Thomas Mercer (Rochester); Roger McClellan (Lovelace); Arthur Tamplin (LLL); and William Lotz (DBM/AEC). It was soon decided that gastrointestinal absorption was so low and that the protection afforded by the cornified epidermal layers in the skin was sufficient to eliminate surface deposition and ingestion as important health problems from this alpha emitter. Inhalation and effects on lung were considered the major concern, although thought was given to gonads to the extent of careful calculations of how much the maximum possible amount from SNAP devices might add to the plutonium already accumulated from weapons-testing fallout. It was considered not sufficient to make much difference biologically.

Obviously, particle size was an important parameter in estimating the inhalation hazard from a reentry burn up of a SNAP device. Many of the ideas that later triggered the hot particle issue came up for full discussion at the meetings of the committee. It was agreed that full burn up would probably result in a predominance of very small particles (i.e., it would be a fume). Thus, hot particles would not be present initially. However, they might form later, either by coalescence in the atmosphere or in the lung. There was also consideration of the size of the populations potentially exposed and of what guidance should be given to agencies concerned in the event of a mishap.

An opportunity to test the calculations came unexpectedly. On April 21, 1964, a navigational satellite carrying a SNAP Device (SNAP 90A, indicated in table 14.3 as "Transit 5-BN-3") containing 17 kCi of ^{238}Pu (about 1 kg) failed to reach full orbital flight. The payload re-entered the atmosphere in the Southern Hemisphere and burned completely (Krey 1967).^(b) Long-term balloon and aircraft sampling and integrated fallout figures determined from samples of soil collected from sixty sites worldwide are told in detail by Hardy, Krey, and Volchok (1972). About 13 kCi could be accounted for, most of it in very small particle sizes that could remain aloft for years (half-residence time, fourteen months). The distribution, while localized in the Southern Hemisphere to begin with, gradually became worldwide, although it never became uniform. Because of the enormous dilution, no inhalation or other health hazards could be identified. Nevertheless, we must remember that none of the larger particles could have still been aloft by the time the sampling program got under way. We must assume that either there were very few of these, or that they fell in areas where they would not be detected (which at the time of the abort was nearly everywhere around the area involved).

The health hazards associated with SNAP devices were probably more thoroughly researched than any nuclear energy undertaking of the day, in proportion to their importance. So far, it appears that the planning and performance have been adequate. Even the one abort seems to have added only to the inventory of plutonium, not to discernible health effects.

(a) He is now at Bonita Springs, Florida. Dr. Bruner's reminiscences on a taped interview were also extremely helpful in this and other areas.

(b) There were two other aborts (see table 14.3). However, the containers remained intact in these instances.

C. More Alaskan Operations^(a)

In chapter 12 on fallout, and elsewhere, we referred to the special food-chain problems in arctic regions that involved vectors such as lichen-reindeer or caribou (or other edible vector)-Eskimo. A fairly large ecological investigation was mounted. Much of it was reported in the third symposium on radioecology, (see, for example, Hanson and Eberhardt 1971; Holleman et al. 1971; Koranda and Martin 1971; Martin and Koranda 1971; and many others). There was similar work in northern Europe, particularly by J. Miettinen of the University of Helsinki, Finland. Some of this was carried out in the interior of Alaska, and some on the coast at Amchitka Island in the far reaches of the Aleutians. Three nuclear tests were conducted on Amchitka Island. The first, "Long Shot" was a low-yield nuclear test conducted on October 29, 1965, for seismic calibration purposes. A few biological observations were conducted relative to this nuclear test by the University of Washington. As told in a personal interview with Allyn Seymour of the University of Washington (1979), one set of observations conducted with the "Long-Shot" test concerned fish eggs that were undergoing embryological development in a stream close enough to the shot to be subjected to considerable jarring and shaking. Some of the capsules were disturbed and moved a short distance downstream. However, the survival was on the order of 90%. Also, samples of fish and plants were brought back to the laboratory for radiological analysis. This was primarily for monitoring purposes to check on possible releases of activity in these unstable rock formations. None were found.

There was little work relative to radionuclides in biological materials in this operation.

The other two nuclear tests, "Milrow" (October 2, 1969) and "Cannikin" (November 6, 1971), were of much higher yield than any underground detonations previously conducted by the United States (Milrow, approximately 1 MT, and Cannikin, approximately 5 MT). These weapons-related tests were conducted on Amchitka because no suitable locations could be found in the conterminous forty-eight states.

An extensive program was conducted to predict and determine the effects of these tests on the bioenvironment. This program was initiated in 1967 by Battelle Memorial Institute (BMI). In 1969, a comprehensive review was conducted of the bioenvironmental questions that should be addressed, and a comprehensive Amchitka Bioenvironmental Program was developed and administered by the NVO of AEC. Principal persons in developing the plans for this program were Jared Davis of NVO, Richard Davidson of BMI, and Melvin Merritt of Sandia Laboratories, Albuquerque, New Mexico, with the assistance of technical experts in various specific fields such as sea otter ecology and North Pacific oceanography. The studies included geology, anthropology, oceanography, marine biology, marine mammals, and radioecology. The principal institutions that participated in the research were BCL; U.S. Geological Survey, Denver and Lakewood, Colorado; Air Resources Laboratory, NOAA, Las Vegas, Nevada; Sandia Laboratories, Albuquerque, New Mexico; Ohio State University, Brigham Young University, Provo, Utah; NVO; University of Arkansas, Fayetteville, Arkansas; Utah State University, Logan, Utah; Northwest Fisheries Center, NOAA, Auke

(a) The author is indebted to Dr. Jared Davis for information and assistance in preparing this section.

Bay, Alaska; University of Washington, Seattle, Washington; U.S. Fish and Wildlife Service, Anchorage, Alaska; and University of Arizona, Tucson, Arizona.

The plans and results were gathered in a volume comparable to the one on Cape Thompson, cited earlier. It was edited by Merritt (Sandia) and Fuller (BCL) and entitled, *The Environment of Amchitka Island, Alaska* (Merritt and Fuller 1977). Besides the discussions directly relevant to the tests, it contains reviews of the long history of the Aleutians, the slaughter of sea otters to near extinction, the ill-advised importation of blue foxes, the effects of World-War-II operations on the delicate ecology of this area, and much else. Only one chapter addresses radionuclides in air, water, and the biota (Seymour and Nelson 1977). Natural and fallout radionuclides and items of special interest such as tritium, radioiron, and radiostrontium were included.

Samples were collected principally from areas considered likely to be contaminated by seepage of radionuclides from the underground detonation sites. The eighty-one types of organisms collected included mammals, fish, birds, invertebrates, marine algae, freshwater and land plants, with total samples numbering several thousand. The most abundant radionuclides in the samples were the naturally occurring ^{40}K and ^7Be , with the most significant manmade nuclide being ^{137}Cs from worldwide and northern latitude fallout. There was no indication of escape of radionuclides from either of the three underground detonations.

The above does not mean that Amchitka suffered no effects from these heavy detonations. There were numerous rock slides, some of which buried living organisms, a section of the so-called bench along the ocean near Shot Cannikin was permanently uplifted to the extent that the littoral area became dry and its populations lost. Two or three lakes were wholly or partially drained. These effects are summarized by Fuller and Kirkwood (1977). However, none of them involved any release of radionuclides or contamination of the environment.

In retrospect, the effects of the earlier activities of man on Amchitka, e.g., World-War-II construction, roads, etc., were more visible and permanent than those of the three nuclear tests. Naturally, it would have been a different story if the detonations had been aboveground instead of several thousand feet below ground.

D. Mississippi Test

There was much interest in the results of a nuclear detonation in a typical salt dome. After much searching, an ideal geological structure was pinpointed near Hattiesburg, Mississippi, at a small town called Baxterville. A small detonation, less than 5 kt, took place in this salt dome (Carter 1979).^(a) The primary biomedical activity was surveillance carried out by the PHS. Primary interest here, too, was in seismic phenomena. There was no release of radioactivity from these shots. The primary reason for describing them here is to illustrate the ubiquitousness of the surveillance activities of the PHS.

(a) This was not included in the list of announced U.S. tests.

VII. Summary and Commentary

There were several projects centered on actual or potential environmental contamination with radioactive materials that were quite different from either the nuclear weapons tests described in chapter 12 or the experimental work described in chapter 13. Most of these have been brought together in this chapter. Although termed "tests," they involved much field and laboratory research. However, they were not rigidly controlled scientific experiments, and for present purposes we thus call them "special tests."

Some of the earliest of these revolved around the potential for environmental contamination with plutonium and other weapons constituents in the event of a nonnuclear detonation (i.e., the high explosive only) of such a device. There were organized tests at the Nevada Test Site in 1956 and 1957 (Project 56 and Test Group 57 of Operation Plumbbob) and a joint U.S.-U.K. operation at the Tonopah Test Range in Nevada (Operation Roller Coaster). These tests were supplemented by two unplanned incidents involving nuclear weapons—one at Palomares, Spain, the other at Thule, Greenland.

Project 56 had no biomedical components. It was aimed at measurement of physicochemical behavior of released airborne plutonium. Test Group 57 generated extensive biomedical data from animals exposed at the time of the one-point detonation and also after chronic exposure for up to 160 days in the contaminated environment. No long-term or short-term effects of the released plutonium could be found, but the period of observation was short. A major conclusion of the experiment was that the potential radiation dose to major organs from cloud passage was of greater importance than that from extended sojourns in a plutonium-contaminated environment. This was the exact opposite of expectations. Also, it appeared that the plutonium content of the air fell rather rapidly with time, also not expected. There were, however, many puzzling inconsistencies in the data and disappointments in the amount learned from the long-term air-sampling program.

Operation Roller Coaster, characterized as the largest inhalation experiment ever undertaken under field conditions, provided good characterization of the aerosols formed and more reliable deposition and clearance kinetics data for lung and other tissues. It seemed to confirm the probably greater importance of cloud passage over later chronic exposure. However, Operation Roller Coaster did not have an extensive chronic phase and, because of the cost and time involved in plutonium radiochemistry, there is still some work to be done.

All of the information from these so-called "safety tests" was used by the military to design configurations for storage and handling of nuclear weapons and for establishment of allowable ground contamination levels of plutonium in case of an incident.

Much effort was expended in the years after these safety tests to evaluate the retention and movement of plutonium in soils and biota in and around these and other sites. This was done largely under the aegis of a managing organization known as the Nevada Applied Ecology Group. This work, too, is still under way, although now reduced considerably in volume. The chapter provides an overview of the principal findings.

Not all of the special tests concerned plutonium or the transplutonic elements. In a little known series of tests at the Idaho Falls site, there were special tests of fission product releases. The *raison d'être* was the now-defunct "Aircraft Nuclear Propulsion Project." It was anticipated that fission products released from a reactor under the conditions of nuclear propulsion might be in quite

different form and behave differently from the fission products in fallout. Elaborate aerosol sampling and measurement facilities were provided, and excellent provisions were made for exposing, caring for, and measuring the radioactivity in animals exposed to releases of fission products. The source was purposely burned reactor fuel elements. The results provided much confirmation of the laboratory work described in chapter 9 but also some differences. The length of time the fuel element had been in the reactor, and the time since its removal, made a large difference in the composition of the released fission products. There were comparable differences in their behavior in the biological systems. This effort was known as "FPFRT" for Fission Product Field Release Tests.

The chapter describes several aspects of Project Plowshare, an extensive and ambitious part of the Atoms for Peace Program. The prime idea was the use of nuclear explosives for giant earth-moving or digging projects. There were extensive computations of possible contamination of the environment and thus the feasibility of digging a new canal between the Atlantic and Pacific Oceans over a route that would avoid costly locks and could be wider and deeper than the present Panama Canal. It appears likely that concern over the lingering contamination did much to cancel this canal project. The pertinent findings are described.

Other aspects of Project Plowshare were several crater-digging experiments at the Nevada Test Site and, most interesting and rewarding, stimulation of the flow of natural gas entrapped underground in impermeable strata by fracturing them with nuclear explosives. The three tests were U.S. government-industry cooperative ventures. They were named "Project Gasbuggy," "Project Rulison," and "Project Rio Blanco." The first was conducted in New Mexico; the other two in Colorado. There is no doubt that the fracturing of the entrapped strata, brought about by nuclear explosion, released appreciable quantities of natural gas. One reliable investigator stated that the process could double the amounts of natural gas available in the United States. The principal radioactive contaminant of the gas was tritium, a radionuclide on the low end of the hazard scale (chapter 10), but not inconsequential. The gas was never used commercially, nor was the process carried beyond the three tests. The idea of piping gas containing even a small increase of radioactivity due to the operations of man into homes and factories was simply not acceptable.

Another category of special environmental test projects concerned the nuclear rocket "Kiwi," which was static-tested at the Nevada Test Site, and an experimental reactor called "ROVER." In these instances, it was demonstrated that possible contamination of the skin with radioactive particles of ^{235}U carbide might constitute the prime health concern. While considered significant, these potential hazards were perhaps less the cause of the project's termination than in some other cases, but the record is murky in this regard.

A large number of conferences, much calculation, and some measurements, were part of the biomedical aspects of "SNAP" (System for Nuclear Auxiliary Power). This project concerned the use of radioisotopes as heat sources for the thermoelectric generation of electric power. The early models used ^{210}Po , but most of the later models used kilocuries of ^{238}Pu .

The program has perhaps been the most successful facet of Project Plowshare. Many space flights have received and are receiving power for vital scientific observations from SNAP units. SNAP power took part in the moon mission (Apollo 17), and units are now in place and powering experiments on the moon. Two Mars landers use SNAP power. In addition, many such units are operating in isolated areas of the earth.

Almost a million curies of ^{238}Pu have been manufactured and placed in these devices. The planning for safety has paid off. The two missions that aborted with these devices aboard ended by burning up in the upper atmosphere with deposit of 17,000 Ci of ^{238}Pu in the stratosphere in one case and recovery of the containers intact in the other. The stratospheric contamination from the first case has exchanged slowly with the troposphere but can still be measured as an entity. It is not considered of biomedical significance.

Other special environmental tests concerned the Alaskan environment and exploration of the effects of a nuclear explosion in an underground salt dome in Mississippi. Not much can be said about biomedical results from these.

These special tests were very costly in money and manpower. There were many who felt that the same expenditure on basic research would have brought greater rewards. It is doubtful, however, if the sources of funds for these operations could have transferred them to other research undertakings. All were bound to specific engineering and safety enterprises. Naturally, the results are harder to get and harder to judge than comparable laboratory efforts. The degree of randomness is obviously greater. Yet, there are those who insist that there is no substitute for tests under field-operating conditions and that they are quite justified. The chronology of results in this chapter should help answer that question.

Note 1—List of Roller Coaster Reports

A. Reports Bearing POR-WT Numbers

Project 2.1 - Soil Deposition

William S. Johnson, Sr.: Project Officer, Eberline Instrument Corporation, Santa Fe, NM: POR-2501 (ST-2501) January 31, 1966, "Official Use Only" (OUO)

Project 2.2 - Air Sampling Measurements

Joseph C. Maloney: Project Officer, U.S. Army Nuclear Defense Laboratory, Edgewood Arsenal, MD, (with participants from General Dynamics, Ft. Worth, TX): POR-2502 (WT-2502) October 21, 1965 (OUO)

Project 2.3 - Fallout Collection

P.W. Krey, Project Officer, R.E. Fried and R.J. Schultz, Isotopes, Inc., Westwood, NJ: POR-2503 (WT-2503) August 23, 1965 (OUO)

Project 2.4 - Micro-Meteorological Measurements (U)

R.W. Titus: Project Officer, U.S. Weather Bureau Research Station, Las Vegas, NV: POR-2504 (WT-2504) July 6, 1965

Project 2.5 - Alpha Survey

W.S. Johnson, Sr.: Project Officer, Eberline Instrument Corporation, Santa Fe, NM: POR-2505 (WT-2505) January 31, 1966

Project 2.6a - Special Particulate Characterization

R.K. Fuller: Project Officer, U.S. Naval Radiological Defense Laboratory, San Francisco, CA: POR-2506 (WT-2506) November 16, 1965 (OUO)

Project 2.6b - Special Particulate Analyses

R.D. Sherwood: Project Officer, Isotopes, Inc., Westwood, NJ: POR-2507 (WT-2507) May 26, 1966 (OUO)

Project 2.6c - Special Particulate Characteristics

C.D. Dunn: Project Officer, Tracer Laboratories Richmond, CA: POR-2508 (WT-2508) September 17, 1965 (OUO)

Project 2.6d - Special Particulate Analyses (Soil)

J.K. Perry: Project Director, Colorado School of Mines Research Foundation, Golden, CO: POR-2509 (WT-2509) May 26, 1966 (OUO)

Project 2.7 - Balloon Support

H.G. Laursen: Project Officer, Sandia Corporation, Albuquerque, NM: POR-2510 (WT-2510) May 21, 1965 (OUO)

Project 2.8 - Off-Site Survey

J.S. Coogan: Project Officer, Southwestern Radiological Health Laboratory, Las Vegas, NV: POR-2511 (WT-2511) September 17, 1968

Project 4.1 - Plutonium Uptake by Animals

R.H. Wilson: Project Officer, University of Rochester, Atomic Energy Project, Rochester, NY

Project 5.1a - Sample Processing Facility

A.L. Baietti: Project Officer, Tracer Laboratory, Richmond, CA: POR-2513 (WT-2513) July 30, 1965

Project 5.1b - Sticky Wire Evaluation

A.L. Baietti: Project Officer, Tracer Laboratory, Richmond, CA: POR-2514 (WT-2514) May 23, 1966

Project 5.2/5.3a - Radiochemical Analysis of Biological and Physical Samples

H.E. Menker: Project Officer, Hazleton-Nuclear Science Corporation, Palo Alto, CA: POR-2515 (WT-2515) May 24, 1966 (OUO)

Project 5.2/5.3c - Radiochemistry

E.L. Geiger: Project Officer, Eberline Instrument Corporation, Santa Fe, NM: POR-2517 (WT-2517) September 17, 1965 (OUO)

Project 5.2/5.3d - Laboratory Analyses of Roller Coaster Samples

P.W. Krey: Project Officer, Isotopes Incorporated, Westwood, NJ: POR-2518 (WT-2518) August 20, 1965 (OUO)

Project 9.5 - Technical Photography

R.P. Beasley: Project Officer, Sandia Corporation, Albuquerque, NM: POR-2519 (WT-2519)

Note 2—Some Reports from the Nevada Applied Ecology Group

Nevada Operations Office, DOE (ERDA, AEC), Las Vegas, NV

Note: Each report contains a series of papers on various aspects of the program. They range from simple progress reports to detailed and sophisticated presentations of

experimental data. There were also many publications in the open literature. Many of these are cited in the ORNL-EIS reports and NVO-192.

ORNL-EIS-72-21 *Environmental Aspects of Plutonium: A Selected Annotated Bibliography*. September 1972. Supplements in 1973, 1974, 1975, 1976, and 1977

NVO-142 *The Dynamics of Plutonium in Desert Environments - AEC Progress Report*. July 1974, USAEC, Nevada Operations Office, eds: P.B. Dunaway and M.G. White

NVO-153 *The Radioecology of Plutonium and Other Transuranics in Desert Environments*. June 1975, NAEG Program Report, USERDA, eds: M.G. White and P.B. Dunaway

NVO-159 *Studies of Environmental Plutonium and Other Transuranics in Desert Ecosystems*. NAEG Progress Report, USERDA, eds: M.G. White and P.B. Dunaway

NVO-167 *Ecology of the Nevada Test Site: A Narrative Summary and Annotated Bibliography*. T. P. O'Farrell and L. A. Emery: Applied Ecology and Physical Center-Desert Research Institute, University of Nevada System, Boulder City, NV; May 1976

NVO-166 *Nevada Applied Ecology Group - Procedures Handbook for Environmental Transuranics*: 2 Volumes. October 1976, USERDA, eds: M.G. White and P.B. Dunaway

NVO-171 *Environmental Plutonium on the Nevada Test Site and Environs*. June 1977, USERDA, eds: M.G. White, P.B. Dunaway, and W.A. Howard

NVO-178 *Transuranics in Natural Environments - A Symposium at Gatlinburg, TN*. October 1976, NAEG, June 1977, USERDA, Eds: M.G. White and P.B. Dunaway

NVO-181 *Transuranics in Desert Ecosystems*. NAEG November 1977, USDOE, eds: M.G. White, P.B. Dunaway, and D.L. Wireman

NVO-192 *Selected Environmental Plutonium Research Reports of the NAEG*. June 1978, 2 Volumes, eds: M. G. White and P. B. Dunaway

ORNL-EIS-127 (NVO/AEIC-7811) *Nevada Applied Ecology Group Publications*. Nevada Applied Ecology Information Center, July 1978, eds: M. G. White and H. H. Pfuderer.

NVO-272 *The Dynamics of Transuranics and other Radionuclides in Natural Environments*. December 1985 (published September 1987), eds. W. A. Howard and M. G. Fuller

 EPA draft environmental statement on normal operations of uranium fuel cycle.
 Reactor safety study (WASH-1400) contains much information on environmental transport.
 Study published on thirty years of environmental transport in White Oak Lake, Tennessee (Dahlman and Van Voris, Oak Ridge).
- 1976** EPA publishes drinking water regulations for radionuclides (40 CFR 141). Radon and uranium omitted.
 EPA hearings on 40 CFR 190.
 EPA issues draft statement on federal guidance for limits of plutonium in soils.
- 1977** ICRP introduces idea of collective dose equivalent.
 EPA document issued on radiological quality of the environment in the United States.
 Los Alamos report on pathways of plutonium from soil to man (Healy).
 EPA issues draft guidance on transuranic elements in the general environment.
- 1977, 1980, 1984** Reviews of resuspension factor work.
- 1978** Comprehensive review of movement of radiostrontium in soils and uptake by plants (Francis, Oak Ridge).
- 1979** EPA standards for uranium fuel cycle, Part A implemented (40 CFR 190).
 Interim soil limits suggested for D&D projects (Healy et al., Los Alamos).
- 1980** UNSCEAR gives detailed tabulations of ⁹⁰Sr transfer functions.
 EPA regulations (40 CFR 190) for uranium mills go into effect.
 EPA proposes clean-up standards for soil contamination (40 CFR 192).
 Discussion of EPA proposals for uranium in drinking water.
- 1980s** Modeling becomes an end in itself.

(a) Depended strongly upon environmental transfer factors.

- 1981 Actinide modeling tried.
- 1982 Publication of Whicker and Schultz's book on radioecology.
- 1983 Publication of Till and Meyer's book on radiological assessment.
Publication of proceedings of NCRP annual meeting on environmental radioactivity.
EPA regulations on active sites (40 CFR 192, parts D and E) become effective.
EPA regulations on uranium fuel cycle, Part B, go into effect (40 CFR 190); concerns ^{85}Kr and ^{129}I .
- 1984 Publication of NCRP report on radiological assessment.
Publication of Kathren's book on radiation in the environment.

Chapter 15

Movement of Radionuclides Through the Environment

Overview

The final chapter of this series of five on radionuclides in the environment considers some of the most complex phenomena of all—the quantitative description of transfer and the development of population dose assessment and standards for population exposure. The basic phenomena are only partly biomedical. Soil chemistry, aerosol physics, meteorology, and atmospheric processes play prominent roles among others, but the internal emitter establishment was deeply involved and worked closely with the other disciplines. Naturally, the chapter emphasizes the biomedical aspects, but there is, perforce, something of nearly everything.

The presentation does not follow a strictly chronological sequence. It was considered best to describe the major systems first, more or less in their present state, and then develop the chronology. Also, since the field is dominated by large compendia developed by government agencies and/or groups of laboratories, the presentations tend to be more anonymous, with less identification of individual investigators than many others in this book. Exceptions are in the earlier, simpler days. Nevertheless, a few institutions and a few individuals are mentioned so frequently that the reader can get a good idea of where the most concentrated areas of activity reside.

There is first a brief description of the major transport pathways, atmospheric, terrestrial, surface water, ground water, and dietary usage factors. This is followed by a general chronology of the development of the systems. The ideas of critical pathways, critical nuclides, and critical populations, and of recycling receive special emphasis. Modeling and the centers for development of modeling are considered next, followed by some highlights for specific radionuclides, e.g., strontium, cesium, iodine, and, as a unit, plutonium, the transplutonics, uranium, and thorium. In connection with cesium, the special phenomena of the arctic food pathway are described. In connection with iodine, the CERT tests at Idaho Falls are discussed in some detail since they have not been generally available. This is followed by an examination of the reduction factors introduced for pathways involving food and recycling of radionuclides that were the basis for Appendix I of the Code of Federal Regulations.

The chapter concludes with a review of population and environmental dose assessments and the development of standards for environmental media or based upon environmental phenomena. The latter include drinking water; the regulation of effluents from light-water-cooled reactors; standards for surface contamination, particularly for plutonium, as developed by the military; standards for contamination of soil; the uranium fuel cycle; and transuranium elements in the general environment. There is a separate section on resuspension and "the resuspension factor" because of the importance of resuspension phenomena in both evaluation and standard setting and extensive amounts of work done on them by all concerned. The gradual shift from occupational to population standards is described, along with some of the controversy that has surrounded the introduction of new very low guidelines by the Environmental Protection Agency.

Fortunately, the quantitative details have been very well described in recent comprehensive compendia, which are cited. Therefore, the chapter introduces only general mathematical relationships and examples of the final results but omits, partly to save space, some of the more complex intermediary processes of derivation. It should be obvious to the reader that this is a very dynamic aspect of the field of radionuclides in the environment and is full of portents for the future. To a degree, it represents a culmination of the research and field work chronicled in the first four chapters of this series on the environment and radionuclides.

I. The Setting

Throughout the pages concerned with observations and research on radionuclides in the environment, we have had occasion to note, in passing, various aspects of environmental transport. Here we will consider the origins and present status of the study of environmental transport processes in their own right and, in form, as much like an entity as can be managed for such a disparate field.

Research in this field has had a very broad base. Indeed, the setting is about as ecumenical as any facet of the saga of the radionuclides. Only the efforts of physicists and chemists in the production and isolation of the hundreds of new elements in the years of World War II and their collaboration with biomedical scientists toward understanding their modes of action and potential hazards had a comparably broad base. In the case of environmental transport, it was the industrial hygienists, aerosol physicists, meteorologists, hydrologists, agrologists and agronomists, oceanographers, and geologists who, in addition to biomedical scientists, supplied the broad base for the initial efforts. More recently, the field has added many varieties of computer scientists, systems analysis experts, and statisticians to become probably the most quantitatively sophisticated (and complicated) of all of the major areas of research on radionuclides. Only the most intricate facets of internal emitter dosimetry have similar claims on quantitative sophistication and, in this author's view, these complexities are less necessary than for the field of environmental transport.

The problems of environmental transport involve from a few to scores of variables. In the early days, rather simplistic analyses could be made by isolating a small segment of the system. With the growing capabilities of systems analysis, computerized calculations, and data storage, larger and larger segments of the environment have been folded in. Each step has involved from some to

considerable modeling, since only a few steps could be described in full without models. Thus, current research regarding environmental transport of radionuclides is rife with modelers and modeling. Indeed, it is a modeler's heaven, for the job cannot be done any other way. As can be expected, the basic scientific questions have sometimes been buried by the models, but fortunately the leaders in the field, at least as it has been applied to radionuclides, have been able to avoid serious excesses in this regard.

It has been suggested, probably by a tired transport modeler, that the calculation of the dose to humans at the end of the environmental transport chain may have more uncertainties than the transport chain itself. This seems most unlikely. The number of variables in the transport equations far outnumber those for ordinary dosage calculations. Their range of variation is as large if not larger. However, when we consider that environmental transport, as a field of endeavor, was essentially nonexistent for radionuclides (except for air transport) until the mid-1950s, whereas problems of dose calculations have been under investigation for much longer, it is surprising that the latter is still less than fully satisfactory (chapters 16 and 20).

Space prohibits any detailed recounting of the present status of the environmental transport field. Fortunately, we are blessed with very recent and adequate summaries that can provide interested readers with all they need to ascertain the present state of the art. Among these in the U.S. literature are the following:^(a)

1. R. J. Garner. 1972. *Transfer of Radioactive Materials from the Terrestrial Environment to Animals and Man*.
2. B. E. Vaughan et al. 1981. *Problems in Evaluating Dose via Terrestrial and Aquatic Pathways*.
3. F. W. Whicker and V. Schultz. 1982. *Radioecology: Nuclear Energy and the Environment*, especially chapter 5 in volume 1 and chapter 1 in volume 2.
4. NCRP. 1983. *Environmental Radioactivity*. Proceedings of the 19th Annual Meeting of National Council on Radiation Protection and Measurements, April 6-7, 1983.
5. J. E. Till and H. R. Meyer, eds. 1983. *Radiological Assessment: A Textbook in Environmental Dose Analysis*.
6. R. L. Kathren. 1984. *Radioactivity in the Environment: Sources, Distribution and Surveillance*.
7. NCRP. 1984. *Radiological Assessment: Predicting the Transport, Bioaccumulation, and Uptake by Man of Radionuclides Released to the Environment*.
8. D. Randerson, ed. 1984. *Atmospheric Science and Power Production*.^(b)

(a) Full references for each are in the bibliography.

(b) In addition to the above, the reader with access to Department of Energy (DOE) documents can find some very concise and very practical summaries in a series of reports from Battelle, Pacific Northwest Laboratories to DOE. Especially complete is a document, "Environmental Dose Assessment Methods for Normal Operations at DOE Nuclear Sites" by Strenge, Kennedy, and Corley (1982). This is part of a largely unheralded and unpublished comprehensive assessment of environmental doses from operations of DOE sites. The referenced report gives a brief review of available models for atmospheric transport and diffusion, waterborne transport, exposure pathways and dosimetry, followed by recommended models for the same parameters. This work is being continually updated to fit the committed dose equivalent concepts (chapter 16).

Several of these carry extensive lists of references. These, plus the symposia cited in chapter 11, the detailed references in chapters 12, 13, and 14, and the several International Atomic Energy Agency (IAEA) symposia to be cited further along in this chapter should meet any need for ascertaining facts.

Unlike most of the other major presentations in this book that could adhere fairly closely to the chronology of events, this subject requires a different approach. We will first introduce the systems more or less as they now exist and then return to trace, in part, some highlights of their development. Also, this field is rife with very large compendia and consolidated efforts of major laboratories or of government agencies. While individual investigators can be identified in the early phases, the literature beginning in the early to mid-1970s has tended to be more or less anonymous, or lists so many contributors to large efforts that it seems unfair to select out individuals without knowing exactly the extent of their contribution. It is clear that of the laboratories in the internal emitter establishment, Hanford, Lawrence Livermore, Los Alamos, New York University, and Oak Ridge were the most heavily involved. Also, recent years have seen the emphasis shift from laboratories to agencies of the government, primarily the Atomic Energy Commission (AEC) and its successor agencies (Energy Research and Development Administration [ERDA] and DOE), the Environmental Protection Agency (EPA), and the Nuclear Regulatory Commission (NRC), plus involvement of the Public Health Service (PHS) for more specialized aspects.

II. The Systems

We will examine briefly the major systems involved in the environmental transfer of radionuclides. They are reasonably obvious but should be set out since most of the analyses tackle primarily one or another of the major systems. They are: (1) the atmosphere and atmospheric transport; (2) terrestrial transport involving soils, vegetation, and animal products; (3) transport in surface waters; and (4) transport in ground water. The ultimate objective is, of course, assessment of the dose to humans. To accomplish this, an entire system of "usage factors" has been developed to apply to dietary and inhalation pathways. Some of this ties closely to dosimetry; e.g., lung model and gastrointestinal tract model, but, in general, the environmental scientists have been content to let their systems bring the radionuclide to the point of its entrance to the human body and let others take responsibility for the final dosage calculation.^(a)

A. Atmospheric Transport

This was the earliest system to be developed in depth. In the days before and during World War II and the early postwar years, it was occupational exposure that commanded center stage. Inhalation hazards were paramount. Ingestion in either food or water was (and is) ordinarily of much less importance for in-plant exposures. The field of industrial hygiene had already made a respectable start in the prewar years around problems of "the dusty trades." Furthermore, wartime research concerning the dispersion of chemical warfare agents had

(a) This distinction is fast breaking down since the environmentalists, understandably, become impatient waiting for someone else to supply estimates of the ultimate dosage to humans from the models they have constructed.

added sophistication to understanding of atmospheric transport, and meteorology had added to understanding of both micro-and macrophenomena. Thus, those concerned with the atmospheric transport of radionuclides had an organized and expanding sister field to tie into. Much of the early work, as well as research today, is applicable equally well to radioactive and nonradioactive materials.

Theories of atmospheric diffusion and dispersion were developed as early as the 1920s. By the time industrial hygiene was becoming a recognized field, reasonable pictures were available to apply to different conditions such as stable air, turbulent air, inversion conditions, lapse conditions, and to the effects of humidity, precipitation, and other factors. For local transport and dispersion, the so-called Gaussian plume model has been and is used extensively for radionuclides. Chapter 2 in Report No. 76 of the National Council on Radiation Protection and Measurements (NCRP) describes this three-dimensional model and six other model types with comments on the geographical scale, frame of reference, type of topography treated, etc. There is still greater detail and still greater generality in the chapter by Brenk, Fairbent, and Markee (1983) in the book by Till and Meyer. A diagram of the coordinate system for a Gaussian plume model is shown as figure 15.1. This model is used in all of industrial hygiene and health physics.

FIGURE 15.1. Coordinate system of the Gaussian plume model, showing distribution of concentration in the horizontal and vertical (after Turner 1969). (Derived from Turner 1969 as pictured in NCRP 1984. Reprinted with permission of the National Council on Radiation Protection and Measurements, Bethesda, Maryland, copyright 1984.)

It is interesting to note that many of the atmospheric transport models of later years are closely identified with, even named after, atomic energy installations. Among these are Hanford, Idaho Falls, Los Alamos, Oak Ridge, and Brookhaven National Laboratory in the United States; the aerosol physics and meteorology groups in England, cited in chapter 14; a group in West Germany (Klug, cited by Brenk, Fairbent, and Markee 1983); and many in the USSR. One reason for this development was the considerable pressure on nuclear energy installations from the very beginning to place special control on airborne releases when micrometeorological conditions were not favorable for rapid dispersion of the effluents. Also, the ease of measurement of radioactivity stimulated many tracer-type applications that involved the nuclear energy community still further.^(a) They were all tied together, however, by ideas and compendia by individuals such as Pasquill (1962, 1974) and contributions from AEC laboratories such as those by Gifford (1961, 1976) from Oak Ridge, the group at Hanford (Fletcher and Dotson 1971b; Soldat, Robinson, and Baker 1974), and Turner (1967) from the PHS. Also, the AEC air cleaning conferences cited in chapter 9 were valuable sources of information exchange (see also Slade 1968).

We must add, of course, that the demands of the research on fallout (chapter 12) stimulated greatly the involvement of the internal emitter community with problems of atmospheric transport on both a local and a global scale. A major portion of the AEC's expenditures on environmental sciences as late as fiscal year 1970 went for atmospheric radioactivity and fallout research (\$8.9 million versus \$6 million for terrestrial and freshwater ecology and \$4 million for marine sciences).^(b)

A few observations, chosen more or less at random, can serve to highlight some concepts and findings of the work on atmospheric transport not already cited in earlier chapters:

1. Several processes contribute to the transport and deposition of material in the atmosphere, not just air movement. These are pictured in figure 15.2, taken from Brenk, Fairbent, and Markee. It should be remembered from chapter 12 that the work on fallout from nuclear weapons tests showed that the bulk of deposition of radionuclides on a global scale came from the processes labeled "washout" and "rainout" in the above figure. By contrast, the deposition in arid climates such as the Nevada Test Site came from "dry deposition," except during the infrequent storms.
2. Much effort was expended on quantitating deposition. This began early, but we tend to associate radionuclide quantitation with studies on iodine. Some of these have been cited in earlier chapters, e.g., early studies at Hanford. The British did much of the basic work. A typical exposition appears in a summary by Chamberlain (1960), who worked at Harwell. This concerned primarily small particles. Other work considered larger particles and wet deposition as well as dry. The literature and models are replete with factors for velocity of deposition measured in centimeters per second. Much detail, but not much history, can be found in chapter 1 of volume 2 of Whicker and Schultz (1982). A recent review by Jones (1984) concerning the Atmospheric Modeling Working Group of the U.K. National Radiation Protection Board indicates that the field is still very active in nuclear energy circles.

(a) All of this was well before the days of the environmental impact statement!

(b) These figures quoted from Whicker and Schultz (1982), vol. 1, chapter 1.

FIGURE 15.2. Atmospheric dispersion and removal processes. (Redrawn from Brenk, Fairbent, and Markee 1983.)

3. The importance of resuspension by wind of particles already deposited on the surface and attempts to quantitate it have occupied the attention of several laboratories in the AEC-ERDA-DOE fold. Indeed, they require a separate description that will be reserved for later discussion (section IV B) in this chapter.
4. Of particular interest in the atomic energy field, but by no means limited to it, is work on the influence of buildings on the air flow over and around them. Typical Gaussian plume kinetics, are illustrated in figures 15.2 and 15.3. These can be badly distorted close to a building, as illustrated in figure 15.4A and B. It is now part of the lore of practical health physics to measure rather than to predict concentrations of airborne radionuclides in such situations.

FIGURE 15.3. Gaussian transport. The diagram on the left represents the approximate outlines of a smoke plume observed instantaneously and of plumes averaged over 10 min and 2 hr. The diagram on the right shows the corresponding cross-plume distribution patterns (Slade, 1968). (From Brenk, Fairbent, and Markee 1983.)

FIGURE 15.4A. (Left) Flow over center of a long, flat building roof for wind perpendicular to the upwind face. (Redrawn from Wilson 1979.)

FIGURE 15.4B. (Right) Model of flow near a sharp-edged building in a deep boundary layer. (Redrawn from Hosker 1979. Further details can be seen in Brenk, Fairbent, and Markee 1983.)

5. The emphasis in study of airborne transport of radionuclides has gradually shifted. In the years of World War II and until the problems of fallout took over, in-plant measurements for development of occupational exposure data were the primary objective. They still are for plants with potential inhalation hazards. But the potential for an inhalation exposure via the environment from releases of fission products or radioactive gases commanded attention. As the work on fallout progressed, the potentially much greater importance of the food pathway for population exposures emerged. The system thus became a two-step one. It considered first the airborne component and then the uptake directly or indirectly into food and the eventual transfer to humans via food.

During the past thirty years, the AEC-ERDA-DOE organization has taken a lead in synthesizing available knowledge on atmospheric transport processes. Its third major reference work, *Atmospheric Science and Power Production*, cited at the beginning of this chapter (Randerson, 1984) provides extensive information on current topics that are outlined in note 1 at the end of this chapter. It is clear that efforts to understand atmospheric transport processes, even those

related to radionuclides, have been very broadly based and not so much an exclusive function of the biomedical community as was true for some of the other environmental areas. Yet, it has been the persistent need for hazard evaluation that, except for pure meteorology and aerosol science (see chapter 9), provided the prime stimulus. It is obvious from perusal of the bibliographies of some of the recent summaries that government is now providing much of the stimulus for the enterprise and that it resides significantly in the radiation protection community. A table in NCRP Report No. 76 (1984) gives a list of nineteen Gaussian models. The developers are distributed as follows:

U.S. Environmental Protection Agency(a)	12
State Environmental Protection Agencies	3
Oak Ridge National Laboratory	1
Lawrence Livermore Laboratory	1
Private Industry	2

B. Terrestrial Transport

Terrestrial transport of radionuclides involves living organisms as transporters as well as final recipients in contrast to atmospheric transport. A major role is played by vegetation, as is obvious from our earlier consideration of the forage-cow-milk-human pathway and others (chapters 12 and 13). A block diagram of terrestrial food pathways considered in one model (Booth and Kaye 1971) is shown as figure 15.5.

FIGURE 15.5. Block diagram of the terrestrial food pathways. (Modified from Booth and Kaye 1971. The symbols used in the detailed model have been deleted. Redrawn from NCRP 1984. Reprinted with permission of the National Council on Radiation Protection and Measurements, Bethesda, Maryland, copyright 1976.)

Even this relatively simple model, which does not attempt to break down the soil into various subcompartments, for example, has twelve transfer coefficients to be evaluated in addition to three source terms (S_1 - S_3) that represent deposition on above-the-surface food crops, on soil surface below the food crop, and foliar deposition on pasture grass. Obviously, while the source terms are indicated as from fallout sources (broadly speaking) and are, therefore, airborne, the source can also be waterborne, thus adding further transfer terms. Note also that factors such as the decay time in milk or beef, and the relative amounts in various parts of the beef, such as bone versus muscle, must be factored in to get meaningful input to humans. These are not shown in this particular model.

(a) By outside contracts in many cases.

There are models to represent transient contamination, such as from a pulsed event, and models for steady state conditions.

Some further insight into the many factors that need consideration in terrestrial food pathway models can be gleaned from the following:

If water is the source of the contamination by drinking, irrigation, etc., we need to know—

- concentration of radionuclide in water,
- concentration factor (accumulation factor) from water to plant or animal, directly or in sequence,
- drinking rate if drinking water is the primary source,
- soil accumulation by irrigation,
- soil accumulation by rainout,
- deposition on foliage by irrigation.

If air is the primary source of contamination, we need to know—

- the several deposition factors outlined above,
- the concentration of radionuclides in air,
- the particle size distribution in air,
- soil accumulation from air,
- if inhaled, the breathing rate and factors for lung deposition and retention,
- concentration factors (accumulation factors) in plant or animal directly or in sequence.

If feed is the primary source, we need to know—

- decay between times of deposition and of harvest,
- fraction translocated from soil to grain or forage,
- decay during storage of feed and thus knowledge of time between contamination and harvest, harvest and consumption, etc.,
- losses in home and commerce.

Factors of importance in the recipient are—

- daily ingestion of each component, e.g., milk, eggs, beef,
- secretion coefficient to milk,
- coefficient of transfer to meat or eggs,
- concentration in each component,
- pharmacokinetics within the body.

Small wonder that elaborate computer programs are needed to encompass even the major transfer factors. Small wonder too that there are many models and many computer programs to accommodate various facets of so broad an input.

We have already seen that soil-plant relationships are very dependent on the chemical composition of the incoming nuclide and of the soil and the conditions of growth. Further factors must be introduced for the duration of retention on leaves, the time between contamination and intake, etc. Details of how these factors are currently used can be found in the key summaries of Till and Meyer (1983), NCRP (1984), and Whicker and Schultz (1982).

In these models, the concentration ratio between plant and soil comes into serious use. Remember (chapters 12 and 13) that values for these were derived largely from greenhouse experiments with confirmatory numbers from field experiments and from the sites of nuclear tests.

Despite the apparently large amount of information accumulated, current modelers have had many occasions to use "default values," i.e., values

prescribed for a model parameter in the absence of data directly relevant to the assessment situation. A range of such default values for eight important radio-nuclides is given in table 15.1.

TABLE 15.1. Range of Default Values of B_{iv} , the Concentration Ratio for Plant Uptake from Soil, F_{im} , the Transfer Coefficient to Cow Milk, and F_{if} , the Transfer Coefficient to Beef^a

Element	B_{iv} ^b Conc. in Wet Vegetation/ Conc. in Dry Soil	F_{im} d L ⁻¹	F_{if} d kg ⁻¹
Co	1×10^{-3} to 9.4×10^{-3}	5.0×10^{-4} to 2.0×10^{-3}	1×10^{-3} to 1.7×10^{-2}
Sr	1.7×10^{-2} to 1.0	8.0×10^{-4} to 2.4×10^{-3}	3.0×10^{-4} to 2.0×10^{-3}
Ru	3.8×10^{-3} to 6.0×10^{-2}	5.0×10^{-7} to 1.0×10^{-6}	1.0×10^{-3} to 4.0×10^{-1}
I	2.0×10^{-2} to 5.5×10^{-2}	6.0×10^{-3} to 1.0×10^{-2}	2.9×10^{-3} to 2.0×10^{-2}
Cs	6.4×10^{-4} to 7.8×10^{-2}	5.0×10^{-3} to 1.2×10^{-2}	4.0×10^{-3} to 3.0×10^{-2}
Ra	3.1×10^{-4} to 6.2×10^{-2}	2.0×10^{-4} to 8.0×10^{-3}	2.0×10^{-4} to 3.4×10^{-2}
U	2.9×10^{-4} to 2.5×10^{-3}	1.2×10^{-4} to 6.0×10^{-4}	1.6×10^{-6} to 5.0×10^{-3}
Pu	1×10^{-6} to 2.5×10^{-4}	2.5×10^{-8} to 2.0×10^{-6}	4.1×10^{-7} to 5.0×10^{-3}

Note that the ranges of the default values are seldom much more than a factor of ten, except for plutonium.^(a) Note also the variety of models referenced to gather the figures shown in table 15.1.

In the U.S. NRC Regulatory Guide 1.109 (NRC 1977), plant-soil concentration ratios are given for thirty-one elements of importance in the nuclear fuel cycle. They range (pCi/kg vegetation ÷ pCi/kg soil) from 5.5×10^0 for carbon to 1.7×10^{-4} for zirconium.^(b) These seldom exceed unity and most indicate discrimination against the metal between soil and plant. This stands in marked contrast to concentration factors in aquatic media that may be very large (Kathren 1984, and earlier chapters) and indicates that transfer is, in general, a selective and idiosyncratic process.

Transfer rates, of course, play a major role in determining these factors. In table 11.4 in chapter 11, we saw that the degree of food-chain transport could

(a) The reason for this greater range may lie in the greater demands that plutonium places on analytical techniques and its tendency to shift valence states in different environmental situations.

(b) Iron is given as 6.6×10^{-4} . This must refer to an insoluble form of iron in the absence of chelators and perhaps in the ferric form.

vary widely among radionuclides. Thus, any transport models for terrestrial systems need to be nuclide-specific to be in tune with present-day requirements. In dealing with mixtures, the old practice of selecting "critical nuclides" can still be applied to some extent (more later) if one is careful.

Concentration ratios from plants to animals are equally element specific. A tabulation prepared by members of the Nevada Applied Ecology Group (Reichle, Dunaway, and Nelson) was reproduced by Whicker and Schultz (1982) and is shown as table 15.2.

TABLE 15.2. Animal/Plant Concentration Ratios for Selected Elements in Terrestrial Ecosystems

Element	Invertebrates			Mammals		
	Sapivores	Herbivores	Carnivores	Herbivores	Omnivores	Carnivores
Ca	0.1 - 18	0.1	0.1			
Sr		0.1	0.1	0.5 - 4.5		
K	3.5	3.0	2.0			
Cs	0.2	0.3 - 0.5	0.1 - 0.5	0.3 - 2.0	1.2 - 2.0	3.8 - 7.0
Na	17	21	27			
Co		0.4	0.5	0.3		
Ru		0.4	1.2	0.4		
Fe				0.8	0.2	
H	0.6			0.6		
P	11	17	18			
Ra				0.01		
I				0.5	0.2	0.1

Source: Reset from Reichle, Dunaway, and Nelson, *Nucl. Saf.* 11, p. 43, 1970 (via Whicker and Schultz 1982, vol. 2, p. 64).

These figures have many problems despite their apparent erudition. As Whicker and Schultz (1982, p. 63 of vol. 2) point out, it is difficult to determine even such simple things as whether or not the basis for the values was wet or dry weight and in many instances the exact plant-food base. Also, these are presumed to be average whole-body contents and would differ for different tissues in the same organism.

Nevertheless, the data illustrate an important point, sometimes the content of the animals is somewhat higher than that of the plants eaten. This is especially notable for elements like potassium, sodium, and phosphorus, whose concentrations in the animal body are regulated homeostatically.^(a) Also, it appears that there are not only differences among elements but some differences between major groups of animals (note, for example, cesium).

(a) Calcium is, of course, also rigidly regulated but happens to be lower in animals than in plants except for some sapivores.

Not all parameters are dependent on the nuclide concerned. In addition to those factors mentioned earlier we can cite:

- crop yield,
- weathering half-life,
- surface density of dry soil,
- build-up time in soil,
- fraction of time cattle are on pasture versus stored feed,
- area that animals, particularly cows, can be considered as utilizing (measured in m^2/day).

We can conclude that terrestrial transfer may be the most complex of those systems requiring analysis. At least it may require the most terms.

C. Surface Water Transport^(a)

This system concerns the transport of radionuclides discharged directly into surface waters as liquid effluent releases, deposition directly from the atmosphere, introduction via run-off from terrestrial deposits or the gradual introduction from ground water transport. The problems of river transport are very different from those of small ponds. Lakes are different from small ponds, and, of course, oceans are different from them all. Estuaries are a unique mix requiring specific treatment. Nevertheless, all of these differ from terrestrial transport (except air dispersion) by having a much higher degree of mobility and mixing over very wide areas.

At least two dichotomies appear. The first is the presence of potential for sizeable external radiation doses from radionuclides in the water, especially if they have been concentrated by biological activities. (Remember the high doses from organisms on the hulls of ships in the Bikini tests, seen in chapter 12?) This is in addition to the usual potential for intake by drinking the water or eating aquatic biota. The second dichotomy is between bottom sediments and the overlying water. Many insoluble radionuclides become attached to particles descending to the bottom, or concentrate in the sediments simply because normal mixing brings them into contact, or they eventuate there after becoming part of the shell or body of an aquatic organism. More soluble forms may remain in solution and circulate for long periods. Thus, we expect to find the transfer factors in aquatic systems very nuclide specific, as they are in terrestrial systems. We can also expect large differences in the biota depending on their feeding habits, e.g., bottom feeders versus others.

All of this became apparent in the work around the sites (chapter 11), in the studies in the Pacific (chapter 12), in laboratory and controlled field research (chapter 13), and in general aquatic ecology.

Biota play a prominent role in transport in surface waters. They may move appreciable quantities of radionuclides, particularly in the oceans and larger lakes where plankton form a considerable part of the biomass. However, it is via the food pathways that biota play their key role in aquatic systems. Food web models, one for ^{137}Cs in a freshwater environment, one for a more generalized web in a lake system, are shown in figure 15.6A and B.

(a) We are including here all aquatic systems that are not underground but obviously excluding the slowly exchanging marine waters below the thermocline.

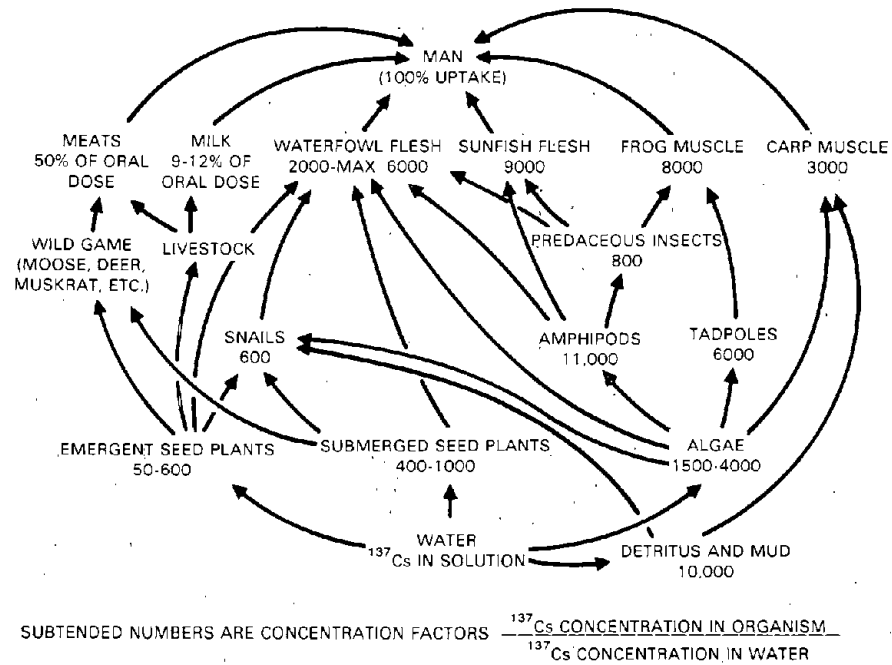

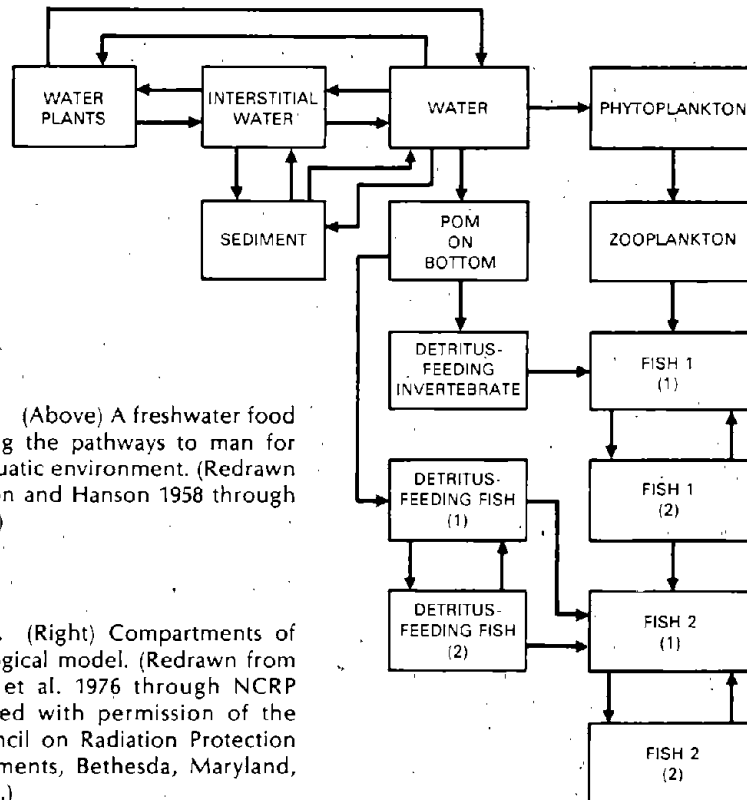

FIGURE 15.6A. (Above) A freshwater food web illustrating the pathways to man for ^{137}Cs in the aquatic environment. (Redrawn from Pendleton and Hanson 1958 through Peterson 1983.)

FIGURE 15.6B. (Right) Compartments of the lake ecological model. (Redrawn from Vanderploeg et al. 1976 through NCRP 1984. Reprinted with permission of the National Council on Radiation Protection and Measurements, Bethesda, Maryland, copyright 1976.)

Concentration (accumulation) factors in the aquatic environment are given in figure 15.6A. They illustrate again the point made earlier that such factors can be very high due, in part, to the very low concentration of radionuclides in the surrounding medium. A listing of concentration factors for over two dozen radionuclides in aquatic plants, crustaceans, mollusks and fish is given by Peterson (1983) in his monumental chapter on terrestrial and aquatic food chain pathways in the book by Till and Meyer. This is followed by a similar tabulation for estuaries and saltwater organisms.^(a)

Despite the emphasis we in biomedical science place on the role of biota, it is quite possible for hydrographers and physical oceanographers to spend entire careers on the physical and chemical transport processes alone. Jirka et al. (1983) list the following transport and transformation processes that affect radionuclide migration and fate in surface waters, none of them involving the biota:

Transport

- water movement
- discharge-induced advection and diffusion
- ambient advection and diffusion
- sediment movement

Intermedia transfer

- adsorption and desorption
- precipitation and dissolution
- volatilization

Degradation and decay

- radionuclide decay

Transformation

- production of daughter products

Even further detail of the many nonbiological processes that must be considered is shown in figure 15.7. This concerns the processes in what is commonly referred to as a water column, a much-worked concept in aquatic ecology and oceanography.

Obviously, much of this physicochemical work has been done by people we have not met elsewhere in this book. Nevertheless, it is surprising to find how many of the institutions familiar to us from efforts at dose assessment and evaluation of health effects have taken part in these aspects also. It has been an area for physical and biological scientists to rub elbows to a considerable extent. The interchange is needed, for all factors must be entered into the models.

D. Transport in Ground Water

The problems of radioactive waste disposal focused more attention on transport of substances in ground water than had ever occurred before. It is true that hydrologists were aware of the basic characteristics of ground water movement and its storage in geological formations or groups of formations known as aquifers. It was known that the movement of ground water could be very slow

(a) While we are accustomed to expect high concentration factors in freshwater systems because of the low concentrations of salts in freshwater, these tables show many values for marine organisms that are equally high.

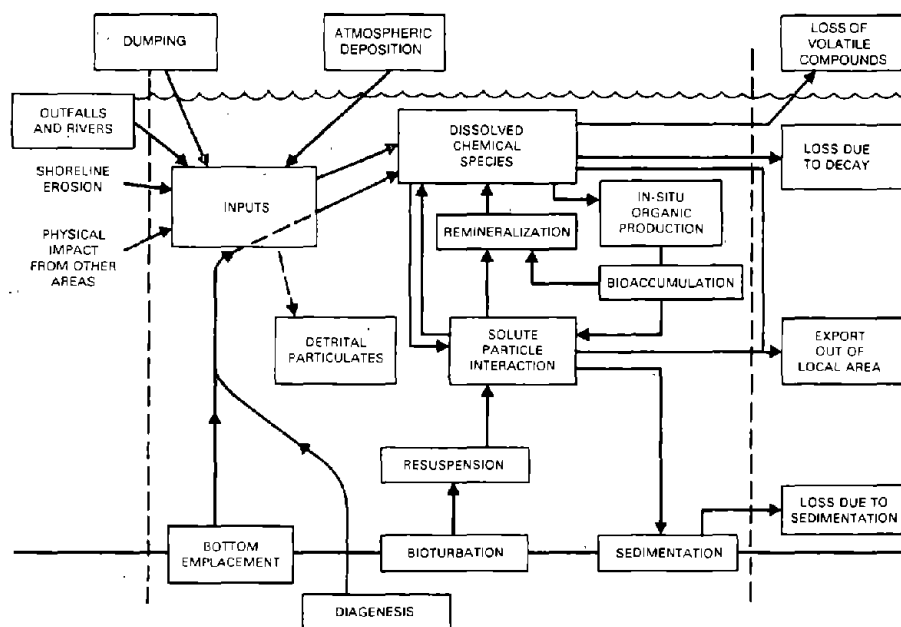

FIGURE 15.7. Possible transformations of a pollutant in the water column. (Redrawn from NOAA 1979 and NCRP 1984. Reprinted with permission of the National Council on Radiation Protection and Measurements, Bethesda, Maryland, copyright 1984.)

indeed, except for the presence of fissures or fractures that might generate underground streams. Nevertheless, the concern over possible movement of radionuclides from the early disposal sites, such as those at Hanford and Oak Ridge, led to much increase in study and financial support for this branch of environmental science. The findings have, of course, spilled over into assessment of the movement of chemical pollutants from disposal sites throughout the world.

Ground water transport problems differ from those we have examined thus far, not only in the slowness of movement but in the time spans to be considered. Because of the long half-lives of some components of radioactive waste (as well as the near-infinite half-lives of stable elements from chemical wastes) the time scale for making predictions can extend to thousands of years.

The role of biota in ground water transport is minor compared to terrestrial and surface water systems: Many volumes have been written and many blue-ribbon committees and symposia have been gathered to address the problems of waste disposal. Except for some surprises as to which radionuclides appear to assume controlling importance as the waste decays over the millennia, this work has not contributed very directly to the main theme of this book. To conserve space, it will be given only brief coverage. A review of some of the factors that enter into equations for the movement of ground water and ground water models will serve to summarize:

1. Tracers, either deliberately introduced or entering from already extant sources, ground water dating,^(a) and mathematical models have been used effectively.
2. Ground water flow can be represented by a set of coupled equations (Codell and Duguid 1983; Codell and Schreiber 1978).
3. Dispersion and diffusion in porous media, including molecular diffusion, can be estimated by entities such as porosity and effective porosity, dispersivity of tracers in different media, adsorption coefficients and distribution coefficients in different media, etc.
4. The models are numerous and complex but can be validated by measurements from existing or newly driven wells or similar means except for the deeper portions of the ground water system. Thus, much field work, is required. Pure laboratory research has less meaning than in the case of either terrestrial or surface water systems.

Sophisticated quantitative descriptions can be found in the chapter by Codell and Duguid (1983), in chapter 4 of NCRP 1984, and more qualitative considerations in the enormous literature on waste disposal (see, for example, Matuszek 1983). It might have been expected that the movement of radionuclides in ground water would be less nuclide-specific than in some of the other systems. However, the difference in chemistry of different soil types combined with differences between elements makes for notable differences in entities such as distribution coefficients. Examples can be seen in table 15.3A and B.

TABLE 15.3A. Distribution Coefficients:^(a) Strontium and Cesium^a

Material and Conditions	K_d (mL g ⁻¹)	
	Sr	Cs
Basalt, 32-80 mesh	16-135	792-9520
Basalt 0.5-4 mm, 300 ppm TDS ^b	220-1220	39-280
Basalt—0.5-4 mm, sea water	1.1	6.5
Basalt-fractured in situ measurement	3	—
Sand, Quartz - pH 7.7	1.7-3.8	22-314
Sands	13-43	100
Carbonate, greater than 4 mm	0.19	13.5
Dolomite, 4000 ppm TDS	5-14	—
Granite, greater than 4 mm	1.7	34.3
Granodiorite, 100-200 mesh	4-9	8-9
Granodiorite, 0.5-1 mm	11-23	1030-1080
Hanford Sediments	50	300
Tuff	45-4000	800-17800
Soils	19-282	189-1053
Shaley siltstone greater than 4 mm	8	309
Sandstone, greater than 4 mm	1.4	102
Aluvium, 0.5-4 mm	48-2454	121-3165
Salt, greater than 4 mm, saturated brine	0.19	0.027

E. Dietary Pathway Usage Factors

The final feature of the systems we have been considering is a fine illustration of the fact that there are few things that are not sooner or later pertinent to the evaluation of the health effects of radiation. Obviously, it does little good to know transfer factors and amounts of various radionuclides in various media, particularly food, without knowing how the intake is partitioned. It started in dosimetry calculations using the lung model, gastrointestinal tract model, etc., as defined in International Commission on Radiological Protection (ICRP) Reference Man (originally "Standard Man").^(a)

More recently, a concerted effort has been made to establish dietary usage factors for infant, child, teen, and adult. There was, of course, some necessary work done in connection with the global fallout studies—largely by the AEC Health and Safety Laboratory and the PHS (later EPA). In 1970, Durbin, Lynch, and Murray at Lawrence Berkeley Laboratory (then Lawrence Radiation Laboratory) did a thorough research on milk and mineral intakes of infants. They used balance studies from many laboratories, including the University of California. The changes with time over the critical first ten months to a year are, of course, considerable. This compendium, more like the product of a large governmental laboratory than a small academic group, is full of important detail, including intakes of calcium, phosphorus, potassium, and calculations for ⁹⁰Sr.

(a) See chapter 16.

In general, the necessary information was gathered by the cognizant government agencies, either directly or by contracts. It has now devolved upon the NRC.

Much has depended on data from a few sources, e.g., Rupp (1980); Rupp, Miller, and Baes (1980); Blanchard (1978); the National Marine Fisheries Service; and older references in the ICRP Reference Man report (see chapter 16).

A contemporary view of Reference Man was presented by Poston (1983) as a chapter in the book by Till and Meyer. A succinct summary of the usage factors for predicting exposures to man was provided in chapter 5 of the NCRP report (1984). The dietary usage factors were based primarily on market basket surveys, plus investigation of family composition and habits. They included "best estimates" for average daily intake of various foods by age group, relative frequency of consumption of various types of milk, age factors, sex factors, regional comparisons, and others. A kind of listing of default values for the average individual and for the maximally exposed individual is contained in the cited NRC Regulatory Guide. Such listings are shown as table 15.4A and B.

TABLE 15.4A. Values for Dietary Usage Factors from Regulatory Guide 1.109 to be Used for the Average Individual in Lieu of Site Specific Data^a

Pathway	Child	Teen	Adult
Fruits, vegetables & grain (kg y ⁻¹)	200	240	190
Milk (L y ⁻¹)	170	200	110
Meat & Poultry (kg y ⁻¹)	37	59	95
Fish (kg y ⁻¹) ^b	2.2	5.2	6.9
Seafood (kg y ⁻¹) ^c	0.33	0.75	1.0
Drinking Water (L y ⁻¹)	260	260	370

^aFrom NRC (1977).

^bFish includes freshwater and marine.

^cSeafood includes aquatic invertebrates.

Note that these are suggested *for occasions when site-specific data are not available*. In the current regulatory climate, it is suspected that few installations would have the patience to gather their own data or the temerity to use it, unless the situation was really unique.^(a)

The need for knowledge of dietary habits must extend also to animals. French (1967) pointed out, for example, that the amount of ¹³¹I ingested by a small herbivorous animal may be as much as fifty times greater than a comparably sized granivore. The more or less unique position of the ruminants was emphasized in earlier chapters and by Garner (1972, p. 44).

There is no doubt that the generation of information on dietary usage has been important. It began during the furor over fallout (chapters 12 and 13). It has been continued ever since in the hands of a few conscientious and meticulous individuals, and under the auspices of institutions that saw the need for some of their research to be aimed at problems with less glamor than description of the latest nuclear particle. The data will find use in fields far removed from the environmental transfer of radionuclides, but we can thank the internal emitter establishment for doing it.

F. Commentary

It should be obvious from the description of the systems developed to describe environmental transport that hundreds of decisions need to be made for the parameters used in the more sophisticated models. The summaries emphasized in the discussion above were done by thoughtful investigators who went out of their way to emphasize the uncertainties of the models and to identify ways to validate predictions made by the models. It is abundantly clear that uncertainties abound.

Just how large these uncertainties may be when the models are used in a predictive mode is summarized by Vaughan et al. (1981), in material provided to the NAS-NRC FREIR Subcommittee II and here reproduced from the abstract of their subsequently published review:

This review is concerned with exposure risk and the environmental pathway models used for predictive assessment of radiation dose. Exposure factors, the adequacy of available data, and the model subcomponents are critically reviewed from the standpoint of absolute error propagation. Although the models are inherently capable of better absolute accuracy, a calculated dose is usually overestimated by from two to six orders of magnitude, in practice. The principal reason for so large an error lies in using "generic" concentration ratios in situations where site specific data are needed.

Major opinion of the model makers suggests a number midway between these extremes, with only a small likelihood of ever underestimating the radiation dose.

... The extremely wide errors associated with predicting exposure stand in striking contrast to the error range associated with the extrapolation of animal effects data to the human being.

Further research must concentrate on reducing these. It is unlikely that anyone will be injured because of these uncertainties, since the more conservative choices have been made at nearly every turn. It does seem likely that totally unnecessary costs and procedures will add to the furor and apprehension about

(a) For example, Windscale (chapter 11), the Marshallese (chapter 12).

radioactivity in the environment if inappropriate models or improper parameters are used. Worse yet is the potential for slavish adherence to some model because it received the official blessing of a regulatory agency. There is still much to be learned about an entity as complex as our environment. Furthermore, the authors of the best summary documents consistently urge against use of a complex model if a simple one will suffice.

In our present situation, we can get far from reality unless those using the systems are aware of the genesis and background of what we now have.^(a,b) We will spend much of the balance of this chapter on historical development of our present points of view. These cannot be traced as inexorable pathways from early trials to present practices. We do not have space for that, nor could it be done with any ease. Yet, it is hoped that some of the connections will be apparent. Many have been described, in part, in earlier chapters.

III. Genesis of the Systems

A. General Development

The chronology of research on transfer factors involving radionuclides in the United States is comparable to that of radioecology reviewed in chapter 11. It began at Hanford. The pioneer work on the Columbia River was aimed more at effects than cycling, at the outset, but quantitation of transfer factors came out

- (a) Good discussions of the limitations of transport models can be found in Whicker and Schultz (1982, vol. 2, chapter 1) and Garner (1972). The latter emphasizes the need for having data from a field study or studies. The former enumerates the uncertainties in some detail and points out that, while it is customary to use "deterministic" transport models (i.e., specific single values are used as input), an alternative is the probabilistic or stochastic model where the inputs are frequency distributions. Of particular importance is the view emphasized by Garner that a highly sophisticated model does not always make for a more accurate assessment no matter what the input data. Some additional models that might interest the reader are one for milk from contaminated pastures by Lengemann (1970) at Cornell; of cesium from fallout to milk by Wilson, Ward, and Johnson (1969) at Colorado State; for strontium and cesium in the human food chain by Aarkrog (1971) in Denmark; and an important comparison of observed versus theorized capacities of the environment for radioactive contaminants by Foster (1973) at Pacific Northwest Laboratory.
- (b) *Note Added in Proof:* We have eschewed any attempt at details of the modeling, except to illustrate the processes involved. As modeling grew, the suggested values for input parameters likewise proliferated. Indeed, two authors using the same basic model could get different results based on their selection of the input parameters. To provide some guidance, or at least information, on practices used by the calculators, DOE stimulated a unified compilation of models and parameters considered appropriate for assessing the potential or actual impact of radioactive discharges to the environment (Miller 1984). This was done in the Dosimetry and Biological Transport Section of the Health and Safety Research Division of Oak Ridge National Laboratory, an organization with much experience in internal dose calculations, as we have seen. It compares exposure pathways; gives models for each of the major pathways outlined in this chapter, along with their components; and provides conversion factors for external dose-rate as well as estimates of committed dose equivalent for internal exposures, doses, or dose equivalents resulting from atmospheric releases of tritium and carbon. It also includes sample calculations. This is a most useful document.

came out as sort of a bonus. There was, in addition, pioneer work on the waste disposal sites, and some of the earliest reports of airborne contamination of the environment came from the Hanford Works. While the river work has wound down with the closing of most of the reactors, the waste disposal sites continue as sources of data. Even in the 1980s, work on "U Pond" on the Hanford reservation continues. We associate the names of Foster, Davis, Hungate, Healy, Nakatani, Hanson, Bustad, and Kornberg with the earlier reports (to name a few) and vehicles such as the Hanford classified reports, progress reports, and publications in the Atoms for Peace Conferences, the national symposia on radioecology, the symposium on Radioisotopes in the Environment in 1960, and an ever-growing crescendo from that point on.^(a)

In 1963, long after the Hanford program in environmental sciences had become lusty, there was an accidental release of 60 Ci of ^{131}I from the PUREX (plutonium and uranium recovery through extraction) Chemical Separations Plant. This brought on the scene a name we have long associated with environmental transfer of radionuclides and the development of modeling, Joseph K. Soldat. In a 1965 paper, Soldat gives a useful vignette of how contamination and transfer problems in that acute release incident were handled. Soon Soldat established himself and his group and Hanford's Pacific Northwest Laboratory (PNL) as a generator of environmental transfer models (see, for example, Soldat 1971).

The Oak Ridge work was largely focused on waste disposal. It did not involve as large a geographical area as Hanford, but, as we saw in chapter 11, it went many miles down the Clinch and Tennessee River systems. The early efforts at Oak Ridge are associated primarily with names like Auerbach, Krumholz, Struxness, Park, and, behind the scenes, Karl Morgan, who spearheaded the fight for support. These were soon joined by Kaye, Dunaway, Olson, Nelson, and more recently, Rohwer.

In due course, the other operating sites, e.g., Savannah River, brought in still different milieu. Eventually, each installation, including each nuclear power plant of the present day can, and some have, added to our information on environmental transfer factors.

Information gained from the experiences surrounding fallout from nuclear weapons tests made invaluable contributions to our knowledge of environmental transfer mechanisms and quantitative data for transfer factors. Global fallout rained indiscriminately on land and sea, and the local fallout from the Pacific tests was, much of it, deposited in the sea. The excellent work by oceanographers and aquatic biologists was added to information already gathered around the sites regarding aquatic transfer processes. However, it was in the area of terrestrial transfer that the fallout situation contributed the most new knowledge. We have traced its development, especially at and around the Nevada Test Site (NTS) and in the Pacific islands, in earlier chapters.

We should mention again that the British contributed much to the early development of the field by their work around Windscale, through both the routine discharges into the Irish Sea and the accidental atmospheric release in October 1957.

(a) A good review of the entire process can be seen in the book by Kathren (1984).

B. Biological Availability^(a)

In the early 1970s, it was becoming evident that there was no "right" way to determine the value of the all-important transfer factors that are ubiquitous in dose assessment models. The problem was that of choosing which one of several different orders of magnitude best represented the transfer ratio, e.g., of ^{90}Sr from soil to plant, or, of ^{241}Am from soil to plant. Indeed, in these cases, published transfer ratios were found to vary over at least three orders of magnitude (Vaughan, Wildung, and Fuquay 1976). In 1971, Price critically reviewed several hundred references of interest in nuclear waste management (Price 1971), eventually retaining 119 reports illustrative of this wide range for any given radioelement. It was clear that neither soil type, plant type, nor soil profile distribution fully explained the differences reported, and experimental artifacts had been ruled out.

At this point, Raymond Wildung, working in the Ecosystems Department of PNL, entered upon a long series of studies on the soil microbial and geochemical processes that underlie soil-to-plant transfer phenomena. He and his colleagues took an operational concept—the transfer ratio—and placed it on a definitive chemical and biochemical basis.^(b) These contributions can be better understood, as can the driving need for using site-specific data, by quoting from the review by Vaughan et al. (1981):

Only a very small fraction of radioelements bound to soils or aquatic sediments are available to biota, but this fraction is variable over a wide range. The concept of biological availability rests on several lines of evidence, but it has been systematized only in the soil/plant system: i.e., (1) ligand formation enhances plutonium uptake and translocation in plant and animal systems (Watters et al., 1980); (2) the small fraction of heavy metals in soils that is actually exchangeable closely reflects soil amendment fractions (Cataldo and Wildung, 1978); and (3) the factors controlling availability are both exogenous and endogenous. Exogenous factors may involve such source term variables as valence state of the radioelement, its molecular form, concurrent presence with chelates or other exogenous complexation agents, and particle size, as discussed earlier. Endogenous factors may involve ligand metabolites of soil microflora and plant roots, and geochemical factors determined by soil characteristics. Similar processes undoubtedly operate in sediment/microflora/detritivore systems of lakes and streams. Related processes may operate also in organism-to-organism transfer of plutonium through sequential food chains; e.g., gastrointestinal absorption of ligand-bound plutonium is significantly enhanced over the inorganic forms of plutonium subject to hydrolysis (Wildung et al. 1979).

At present, the chemical basis for biological availability deals mainly with plutonium (Watters et al., 1980) and heavy metals (Cataldo and Wildung, 1978). One may expect that similar processes will be common to any radioelement whose chemistry is primarily controlled by hydrolysis or whose electron configuration favors complex ion formation. Among the long-term or large radiological contributors to dose, this includes isotopes of uranium, plutonium, and americium in the actinide series; strontium, cesium, and cadmium; and nickel, iron, and cobalt in the transition series. Complexation with soluble ligands may maintain the solubility of several of these elements, and thus compete with their sorption to soil and sedimentary

(a) This section was supplied by Dr. Burton E. Vaughan, PNL.

(b) Dr. Wildung received the E.O. Lawrence Award in 1982 in recognition of these contributions and advancement of our understanding of the environmental behavior of plutonium.

particles. Such reactions do not necessarily increase their biological availability from [soil solution or] the water column; i.e., larger complex ions may not be biologically absorbable whereas the small ones may be. Clearly, a great deal depends on the type of polymer or complex ion formed, which in turn is a strong function of chemical and biological properties of particular [media] . . .

One very pragmatic corollary of these investigations is that exogenous contaminant will be much more biologically available than the same element as an endogenous constituent of soil. This has been proven for many heavy elements by use of soil amendment procedures (Cataldo and Wildung 1978). Most of the endogenous elements present in soil are simply unavailable to green plants—a greatly overlooked point. The concern about enhanced biological availability is by no means restricted to soil processes. As indicated above, enhanced gastrointestinal absorption of plutonium has been observed when the plutonium was present as an organically bound plant ligand.^(a)

C. Critical Pathways, Critical Nuclides, Critical Populations

In the chapter on fallout, we became aware of the need to select, very early in the work, certain radionuclides as “critical.” The entire spectrum of fission products was, of course, far too extensive to attempt detailed study of every one.

The ICRP is usually credited with formalizing the simplifying concept of selecting certain pathways and populations, as well as nuclides, for primary attention and designating them as “critical.” Committee-4 of ICRP developed a report on environmental monitoring (ICRP 1965) that recommended concepts and procedures for such monitoring.^(b) Since there are a few nuances of language that are important, let us quote from the ICRP’s comments on their recommendations:

The exposure of an individual is a function not only of the levels of radiation and radioactivity in his environment, but also of the individual’s use of that environment and of his personal habits. The Commission recognized this difficulty in paragraph 39 of ICRP Publication 6, and suggested a procedure for assessing and controlling individual exposures. This procedure involves studying a sample of the exposed group and setting the environmental level so that no individual in the sample receives any excessive exposure. This method has sometimes been used satisfactorily, but has proved somewhat arbitrary, especially when the exposed group contains individuals with a wide range of habits.

Most installations which handle radioactive materials are designed and operated to contain the radiation and radioactive materials, and to concentrate their by-product wastes. Nevertheless, some release of radioactivity to man’s environment occurs, due either to the disposal of low activity wastes or to accidents. The releases are made to many different sectors of the environment and the amounts and compositions of the releases will vary from installation to installation (even between installations of the same general type) and from time to time.

- (a) [We saw in chapter 13 that there are, for some radionuclides at least, solubilization processes that occur over relatively long periods of residence. This was particularly noted when the element had been through several uptakes and harvests. This does not conflict with the statement made above concerning greater availability of exogenous contaminant.]
- (b) It will be recognized that some of them were already in use. The concept of critical group was reiterated in ICRP Publication 9 (ICRP 1966).

Thus, in most situations in which radioactive materials are introduced to man's environment, there will be numerous and complex pathways by which each of the released nuclides may ultimately cause radiation exposure of man. An example of such a pathway is the deposition of strontium-90 on grazing land, its direct retention on grass or its uptake into the grass from the soil, its ingestion by cows and the subsequent ingestion of cow's milk by people, especially children. Further examples are given in Appendix A. A comprehensive and detailed study of all such pathways will not be needed, even for installations which involve potential radiation hazards of the greatest magnitude, e.g. reactors, reactor fuel reprocessing plants and stores of fuel reprocessing wastes. Experience has shown that a study of the situation will indicate that certain nuclides and certain exposure pathways are much more important than others. These nuclides and pathways are designated "critical."

The presence of a critical nuclide in some critical pathway will not cause the same exposure of each member of the population outside an installation, and preoperational investigations will usually establish the existence of one or two groups of people whose characteristics, e.g. habits, location, or age, cause them to receive doses higher than those received by the rest of the population outside the installation and thus require them to be considered separately, i.e. to be designated as critical. Great judgment is necessary in defining such a group in practice and the following aspects will have to be considered. Some of these are the same as the factors influencing the design of routine surveys and only those concerned with the critical group itself are listed below:

- (a) The location and age distribution of the potentially exposed group.
- (b) Dietary habits, e.g. special foodstuffs and amounts consumed.
- (c) Special occupational habits, e.g. the handling of fishing gear.
- (d) The type of dwelling, e.g. shielding characteristics.
- (e) Domestic habits, e.g. time spent indoors, frequency of personal washing and laundering of clothes.
- (f) Hobbies, e.g. sport fishing or sunbathing.

Such groups in the population may be in the vicinity of the installation or at some distant location; they may include adult males, adult females, pregnant women, and children; they may be individuals who eat foodstuffs prepared in a special way or produced in a particular location; or they may be people who work in a particular industry. Only general guidance can be given on the considerations needed to define the critical group and the associated critical nuclides and pathways, for the situation will be specific for each installation and its environment, but the importance of such a definition is considerable. The concept of the critical group provides a sound and practical way of complying with the Commission's recommendations concerning members of the public. It also allows economies in the conduct of environmental monitoring.

The critical group should be identified in such a way that it is representative of the more highly exposed individuals in the population and is as homogeneous as practicable with respect to radiation dose, that is, with respect to those factors which affect the dose in the specific case considered.

Once a critical group has been identified in this way, a suitably representative sample of the group should be selected and studied so as to assess their actual or potential exposure. The average exposure of such a sample should then be regarded as typical of that of the highly exposed individuals and the Commission's recommendations for the maximum permissible doses for individual members of the public applied to that average. The spread of values in the sample will give some measure of its homogeneity with respect to the characteristics which have been studied. It must be recognized that there are many characteristics of the individual (such as metabolic rates) which may influence the dose received and which are not measured. These individual differences may tend to increase the spread of

the individual doses received within the critical group. It must also be recognized that, outside the critical group, there may be a few individuals whose habits and characteristics are dramatically unconventional. Such peculiarities may sometimes mean that these individuals receive doses somewhat higher than those to the critical group. It is expected that methods of waste management will be determined not by the possible exposure of these individuals but rather by the dose to the critical group. (ICRP Publication 7, 1965, references and cross-references omitted.)

The ICRP points out that this procedure departs slightly from the idealized aim of not allowing any single individual to receive more than the upper limit of dose but views the procedure as coming reasonably close to this objective. They also point out the then-current limitations of standard man (Reference Man, chapter 16) and suggest use of idiosyncratic data if necessary.

A simplified diagram of the more likely pathways was presented as an Appendix to the ICRP report and is reproduced as figure 15.8A and B.

FIGURE 15.8A. Simplified diagram of potential critical pathways to man for radionuclides released to ground or surface waters (including oceans). (Modified from ICRP 1965. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1965.)

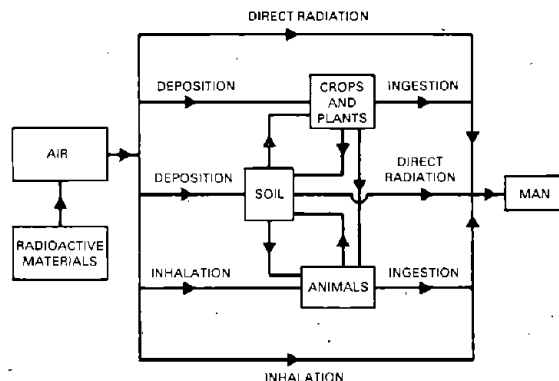

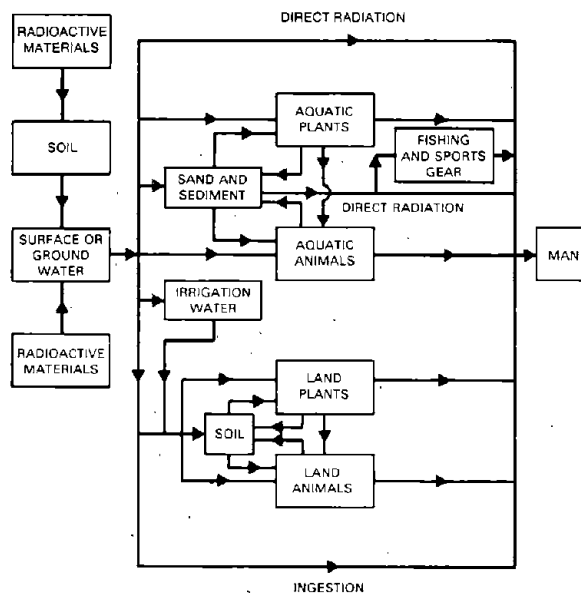

FIGURE 15.8B. Simplified diagram of potentially critical pathways to man from radionuclides released to the atmosphere. (Redrawn from ICRP 1965. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1965.)

In a wide-ranging discussion of criteria for the control of radioactive effluents given at an earlier IAEA symposium, Morgan and Struxness (1971) present a slightly expanded description of the ICRP critical group idea:

The critical group in the population is that group of individuals relatively small in number and reasonably homogeneous that is considered to receive the largest dose to critical body organs and/or to receive the greatest damage from the radioactive contamination. Some of the facts which must be considered in selecting this critical group are location and age distribution, dietary habits, special occupational habits, type of dwelling and heating equipment, domestic habits, hobbies, etc. The critical group may for example be limited to males, females, pregnant women or children of a given age. It may be individuals who eat certain types of food, religious groups that follow certain customs or persons with certain illnesses which affect their habits or metabolism. In any case, it is recognized that due to individual variability there will always be some spread in the dose received within such a critical group in spite of the fact that it is relatively homogeneous from practical considerations. The Commission allows half of the members of this critical group to exceed its dose limits in that the average dose of the critical group may be equal to but not greater than the dose limits given in column 3 of Table VIII. It recognized further that there will always be some members in a large population which have peculiar habits which markedly enhance radionuclide uptake, for example, an individual who may obtain a large fraction of his food from fish soup in which the bones as well as the flesh of the fish are consumed. In such cases the doses he receives may be considerably greater than the recommended dose limits even though the ICRP's recommendations are complied with in that the average dose received by the critical group does not exceed these limits. This recommendation of ICRP is perhaps less restrictive than the AEC Regulations. (Morgan and Struxness 1971, pp. 225-226)

Further along we find important practical advice:

The ICRP has indicated that it usually is not necessary to carry out very extensive environmental monitoring at reactor and isotope facilities, but in preplanning and in subsequent studies to confirm the accuracy of calculations and the safety of an operation, it is essential that a number of various types of measurements be made to assure that the critical segment of the population has been properly identified and that no factors of reconcentration have been overlooked. (Morgan and Struxness 1971, p. 227)

Buried in the long and detailed discussion by Morgan and Struxness (p. 221) is the following:

Since any worthwhile enterprise of man is possible only by accepting certain inherent risks, the nuclear energy industry probably is no exception. The choice, therefore, seems to be between these relatively small hypothetical risks of the nuclear energy industry and the very real risks of power shortages or a smog polluted environment and the associated respiratory diseases we might expect from fossil fueled power plants.

A sound philosophy for 1970 and just as sound for the present, when perspective seems ever more elusive. It will be recognized that the diagrams in figure 15.8 depict only very general pathways. These did seem to be sufficient for the original objectives of the ICRP plan. For more sophisticated applications, a more finely tuned system was needed to feed into the developing computer codes. For example, if ingestion was determined to be the critical pathway, which one was critical? Was it animals to humans or plants to humans? Was it plants to animals to humans? Was it a product of animal activity such as milk? If it was the grain pathway, what grain? Any of these could be "critical" for different radionuclides and for different circumstances.

More difficult than the designation of critical pathway in practice was the designation of the critical group. Sometimes, as we have already seen with the

laverbread eaters around Windscale, the critical group in the population may be small, yet their presence may control an entire operation. Indeed, the British apparently did control to the single individual with the highest potential exposure before ICRP 7 was published (Preston, Mitchell, and Jeffries 1974).^(a,b)

The selection of critical nuclide can be made site-specific, but, for general environmental contamination, it can follow much the same course described in chapter 12 for choosing which of the thousands of radionuclides produced in fission should be concentrated upon. The United Nations Scientific Committee on the Effect of Atomic Radiation (UNSCEAR 1962) judged potential importance of radionuclides by the following:

- production yield and half-life (as described in chapter 12);
- date of entry into food chains after deposition on earth's surface;
- extent of entry into foods of animal origin, such as milk;
- extent of absorption from the gastrointestinal tract and time of retention in man;
- fraction deposited in critical organ and time of retention therein.

On this basis, essentially the same line-up of radionuclides came out at the final step, i.e., receipt by humans, as in the early days of the characterization of fallout. In addition, tritium and krypton were studied carefully, not because of their potential toxicity (see earlier chapters), but because of their mobility in the environment. They could thus be used as what I will term "marker-nuclides" since they may signal the movement of contamination along a path. In addition, some shorter-lived radionuclides (^{89}Sr , ^{140}Ba , and especially ^{131}I) can potentially be critical soon after release.

An examination of how well the ICRP operational system was working or might work came, in part, in work by Preston, Mitchell, and Jeffries (1974) and a companion study by Beach (1975) of the U.K. National Radiological Protection Board. Preston and Jeffries (1969) looked in depth at the critical exposure pathway around Windscale. They did exhaustive analyses of the sources of raw material for the laverbread, its production, distribution, and marketing, a job that suited well the capabilities of the Fisheries Radiobiology Laboratory at Lowestoft where they worked. They chose a critical group of adults in line with ICRP-9 recommendations (children were shown to receive a lower dose) and assumed they derived their laverbread entirely from the source of highest cesium concentration, viz., Cumberland. The estimated doses were from 0.4 to 0.7 rem/yr to the lower large intestine during the period 1962-1967. Since the dose limit to individual members of the public recommended by the ICRP was 1.5 rem/yr, and the assumptions were very conservative, they could conclude (although they did not do so overtly) that the system was working. The later

- (a) While the critical group was fairly carefully described by ICRP, the characteristics of a "suitable sample" (see quotation) seem to have been left more or less loose. Presumably these evaluations would always have the benefit of competent statistical advice, but it appears that intuition may have had to play a role in many instances. Perhaps we should not decry this, for no serious mistakes seem to have been made. It may be one of the last times unbridled intuition could compete with computers.
- (b) *Note added in proof:* Hunt and Shepherd from the United Kingdom (1980) expanded considerably on identification of critical groups and have, to a degree, negated the hiatus in ICRP recommendations mentioned in the preceding footnote. They give several alternative methods for selection.

study (Preston, Mitchell, and Jeffries 1974) did not measure or calculate radiation dose. It focused on identification of the critical group and concluded that unless there were at least eighty observations made "the result will be based on less than two known individual's habits" and that the exceptional individual may well control, despite the formality of choosing a group.

The work by Beach (1975) considered radiation doses. The consumption rate of laverbread was measured along with the radioactivity of the *Porphyra* from which it was made. This established a critical group size, viz., thirty, and from this they estimated that the annual collective dose to the lower large intestine of the laverbread consumers was 266 man-rem.

In a panel discussion at the New York symposium already cited (see Morgan and Struxness 1971), Herbert Parker (Battelle) asked about the probability of there being significant undetected critical pathways. This touched on one of the constant worries of the ICRP's approach and brought several answers. E. E. Pochin (United Kingdom) described the increasing scale of whole-body-counter studies and the efforts to find sites of long-term retention of radionuclides that might have been overlooked. He opined that the only chances for a surprise were with low concentrations and long retention of isotopes with long physical half-lives.

L. Rogers from the AEC's Division of Reactor Development described broad studies of several operating reactors being done by the Environmental Health Service of the U.S. Department of Health, Education and Welfare (PHS) to identify *all* radionuclides in the environment and detect any unexpected concentrations. None were found.

A. Preston (United Kingdom) remarked on the surprise they got concerning the increasing amounts of cesium in effluents from Magnox power stations. It had developed during long burn-up times of the fuel and was not anticipated in the first estimates. Hence, the admonition was made to keep measuring and checking and not assume that nothing new will turn up in nuclides, pathways, or populations during the operation of a facility, no matter how carefully planned.

Despite the possibilities, it seems unlikely that the critical pathway-nuclide-population approach missed important events. However, like the critical organ approach for dosimetry, which has now been abandoned by ICRP, the act of choosing may require choices between nuclides, pathways, or groups that are of quite comparable importance. Thus, contributions of close competitors may be neglected. Indeed, the contributions of several such could exceed those of a single "critical" choice. These situations may be the primary drawback of the original ICRP approach. Doing many pathways is no problem for the sophisticated systems of the present that allow simultaneous calculations for several pathways, several nuclides, and several populations.

Throughout the years of application of the critical pathway approach, and despite the implication that individual operators and modelers should try to be very site specific, the regulatory atmosphere did little to encourage such originality. As a result, the calculations for practical use tended to be largely generic and were individualized only for very special cases. Very recently, Bernard Cohen, University of Pittsburgh, has checked on the merits of an alternative approach to pathway analysis for transport of elements from soil to human diet (Cohen 1985).

This alternative approach used only the average daily ingestion of each element and its abundance in soil, i.e., \bar{I}/C_s where \bar{I} is the average daily ingestion of

element X by the U.S. population and \bar{C}_s is its average concentration in U.S. soil. The results were compared to those obtained by the more complex pathway analysis system. They were consistent with each other within a mean factor of four, "which is roughly the standard deviation in estimates from the pathway analysis." This confirms the intuitive feeling that many have held that we may have become too elaborate in our application of pathway analysis. However, more work and the reaction of the environmental establishment is needed before such conclusions can be drawn firmly. Cohen points out that each method has important advantages in some applications.

D. Recycling

The idea of a critical pathway implies or subsumes, even though the ICRP did not state it overtly, a straight line, "once-through" mechanism. Very early in the development of radioecology it became apparent that cycling and recycling of radionuclides (as well as stable elements) were integral and important parts of the ecosystem processes. Recurrent transfers occur between ecosystems and within the components of a given ecosystem. Sometimes the end result was referred to as "reconcentration" and was a cause for concern, as we saw at the end of the quotation from Morgan and Struxness on page 1285. A very adequate description of the basic phenomena, including mathematical descriptions of the processes, is given in the book by Kathren (1984, pp. 251-254) under the heading "Biological Turnover."

Auerbach (1965) points out that the facts of recycling emerged from at least four lines of investigation: (1) analyses based on the movement of fallout radionuclides at different trophic levels, (2) tracer experiments done to elucidate links in food chains, (3) studies of rates of turnover of specific nuclides within a single trophic level, and (4) tracer experiments done with complete cycles within an ecosystem. The early work was described at the two Atoms for Peace Conferences, the symposium on radioecology at the University of Minnesota, the early U.S. national symposia on radioecology (all cited in chapter 11), and the fourth Hanford biology symposium entitled "Radiation and Terrestrial Ecosystems" held in 1965 and listed along with other Hanford symposia in chapter 8. Historical development is described also by Mitchell (1974) and courses through most of the review by Auerbach just cited. We will see a few further details when we consider specific pathways.

Rice (1965), referring to cycling of radionuclides in the marine environment, emphasized that:

Each radionuclide takes a characteristic route and has its own rate of movement from component to component prior to coming to rest in one of the three components of the marine environment [solution or suspension, sediments, or biota]. Plants and animals to be of any significance in the cycling of radionuclides ... must accumulate the radionuclide, retain it, be eaten by another organism and be digestible. (Rice 1965, p. 953)

Auerbach goes out of his way (1965, p. 1356) to emphasize that the cycling process is considered to regulate and to maintain ecosystems "in a steady state within particular climatic and physiographic zones." A corollary is that errors can be made if transfer factors or other quantitative parameters are deduced from a system that is not in a steady state. Frequently, as with local fallout or single contaminating events, there is no chance of a steady state existing. This

does not mean that pathways cannot be mapped, only that due cognizance must be taken of the situation. It has been.

An obvious way to handle the cycling problem is to break the system down into compartments between which transfer takes place. Thus, the familiar fallout forage-cow-milk-human pathway was analyzed, as we saw for ^{90}Sr in chapter 12, compartment by compartment. However, in the setting of standards and other regulatory operations, a single factor representing the entire pathway may be employed. This has grown out of the mountains of work all over the world already alluded to. In using any single factor, it must always be remembered, however, that each component may be subject to recycling phenomena, and what is used may be the result of several processes. Indeed, it usually is. Examples are numerous. They have evolved in complexity and comprehensiveness from the early days of fallout to the massive compilations produced by the Lawrence Livermore Laboratory, Oak Ridge, and others, to be discussed in the next section.

E. Some Landmark Modeling

1. Lawrence Livermore Laboratory

Since the Biomedical Research Division of the Lawrence Livermore Laboratory (at that time Lawrence Radiation Laboratory) was developed with a charge to enter comprehensive studies of environmental contamination due to fallout, much of their earlier efforts went into modeling.

There was a series of laboratory reports that estimated the maximum contamination of agricultural land from fallout (Tamplin 1967), the maximum dose from internal emitters (Ng and Thompson 1966), biological guidelines for device design^(a) (Burton and Pratt 1968), a large handbook for estimating the maximum internal doses from radionuclides released to the biosphere (Ng et al. 1968),^(b) and estimation of the maximum dose from internal emitters in aquatic food supply (Tamplin, Fisher, and Chapman 1968).^(c) All of these used the format of developing both preshot prediction and means for postshot evaluation and were comprehensive. No radionuclide was dismissed as unimportant unless and until a critical analysis proved it to be. This meant running through all of the radionuclides produced and all of the potential pathways. Postshot predictions

(a) The biological guidelines for device design involved amounts of material, particle fluxes, choice of the least hazardous of several possible design materials under worst possible case assumptions, which cross sections might be important, etc. This was an unusual crossover of biological scientists into details of device design, but the Lawrence Radiation Laboratory has routinely made a point of ignoring the lines between disciplines. The idea of designing a device around minimal biological hazards was, of course, part of the Plowshare philosophy (chapter 14).

(b) This was a document full of tables and utilized the "unit-rad deposition" concept, the minimum deposition of each isotope in $\mu\text{Ci}/\text{m}^2$ that could result in a thirty-year internal dose of 1 rad to the organ or tissue under consideration. Other tables ranged from metabolic data derived from Standard Man (Reference Man—chapter 16) and the uptake and distribution in organs to fraction of intake secreted in milk, ratios of aquatic diet to terrestrial diet, concentrations in terrestrial foodstuffs, seawater foodstuffs, and freshwater foodstuffs. The unit-rad deposition was calculated for both the forage-cow-milk pathway and the soil-root pathway.

(c) For this one they chose, for illustration, the thirty-year dose to infant's bone from an event such as the construction of a sea-level canal with nuclear explosives.

had to be reliable with no "surprises" at short or long times or great distances.^(a) Thus, both preshot predictions and postshot documentation were extended to distances of two thousand to three thousand miles from the point of detonation.

Obviously, this enterprise was closely related to the pathway and dosimetry analysis carried out slightly later at Oak Ridge in connection with Project Plowshare, especially around the potential for construction of a sea-level canal in Panama or Colombia described in chapter 14.

Some years later, a sixth part to this classic compendium appeared. It concerned the transport of nuclear debris by surface and ground water (Fisher 1972).

2. Modeling at Oak Ridge

In addition to the modeling and pathway analysis aimed specifically at possible use of nuclear explosives, described in some detail in chapter 14, the Oak Ridge environmental sciences people extended their modeling to more general situations. It was built upon the Livermore work on assessment, especially that in UCRL-50163. The product was a "cumulative exposure index" (CUEX) for assessing environmental releases of radioactivity (Kaye et al. 1971). It utilized the EXREM and INREM computer codes for dosimetry described in chapter 14, an atmospheric dispersion model called AIRMOD, a terrestrial transport model called TERMOD, and it could apply to single exposure or multiple exposure modes and to many radionuclides and several pathways. The authors consider CUEX as a more thorough and realistic system than the maximum permissible concentration (MPC) because all modes of exposure are included, not just an MPC for air or for water. Also, the MPCs are basically derived from models used for occupational exposure with a scaling factor to the general population.

The CUEX methodology was tested against actual monitoring data from several sites (Parzyck, Witherspoon, and Till 1976). These were Haddam Neck pressurized water reactor (a boiling water reactor), the CP-5 reactor at Argonne National Laboratory (tritium), and ¹³¹I and gross alpha concentrations in the vicinity of Oak Ridge National Laboratory (ORNL). The estimated concentrations and doses were usually within a factor of two of the measured values.

The developers of CUEX indicate that it would need to be calculated for each type of release at each site. "It is not envisaged for general application to all or most situations as the ICRP's Maximum Permissible Concentrations . . . are applied (somewhat erroneously)" (Kaye et al. 1971, pp. 7-8).

A related model called CUMEX (cumulative hazard index), in contrast to CUEX (cumulative exposure index), was developed by the same group and applied to nonnuclear hazards, such as cadmium (Walsh, Killough, and Rohwer 1978).

Both the Lawrence Livermore and Oak Ridge efforts represent something of a zenith of pathway and dosimetric analysis. They put to shame the relatively superficial efforts and approaches applied at the time in the field of environmental contamination by chemically toxic substances, with the possible exception of cadmium. Only now are comparable enterprises appearing on that front.

3. Reactors and other Nuclear Facilities

Some of the earliest efforts at modeling concentrated on analysis of the hazards of environmental contamination from nuclear facilities. At the first Atoms for

(a) They were determined there would be no instances like the iodine-in-milk situation that occurred in Utah (chapter 12).

Peace Conference in 1955, Parker gave a condensed overview of the types of potential hazards from various types of reactors, from chemical processing plants, etc. This included details of atmospheric dispersion work done at Hanford (Parker 1956). Parker and Healy (1956) described the environmental effects of a major reactor disaster, including health effects and estimates of property damage. Both required some basic modeling work. Details of the calculations were given by Healy (1957) in a Hanford report.

In the ensuing years, many and increasingly sophisticated analyses took place. At the second Atoms for Peace Conference, Leonard (1958), from Convair-Fort Worth, used predictive methods for assessment of hazards associated with fission product release. Many others appeared over the years. Some have been referenced in earlier chapters.

A landmark effort occurred in preparation of the Reactor Safety Study carried out by AEC but released by the Nuclear Regulatory Commission in 1975 (NRC 1975). There were external and internal dosimetry models and a chronic exposure model that considered the behavior of radionuclides in soils, the plant-root-milk pathway, and differential equations for a compartment model. Other major reports from the U.S. government were those on the nuclear fuel cycle, the liquid metal fast breeder reactor, etc. In a sense, every environmental impact statement of recent vintage contains elements of one or more of these models.

F. Specifics Regarding a Few Pathways

We could not help but introduce some details regarding specific nuclides in specific pathways while discussing other major topics in these chapters on the environment. Yet, there are areas of research and of scholarly reporting and analysis that we have not reviewed. A few of these form the substance of this section.

1. Strontium Isotopes

In chapters 12 and 13, we discussed the relationship of strontium to calcium, discrimination for calcium and against strontium in the biosphere, and the reasons for considering its two significant isotopes, ^{89}Sr and ^{90}Sr , as "critical radionuclides." We looked briefly at its appearance in the transfer through foods, especially milk, and its effects in animals. We remarked on the contributions its study had made to understanding the biochemistry of bone. Is there anything left to discuss? Of course there is.

First, let us look at pathways for radioactive strontium other than milk. In Russell's (1966) classic early volume called *Radioactivity and Human Diet*, Comar (1966) remarks that deposition of strontium in meat and eggs makes a small contribution compared to milk because these provide only a small portion of dietary calcium. There seems to be little or no discrimination between strontium and calcium between the circulating fluids and soft tissues, or the components of eggs.

Perhaps the most comprehensive and consistent review of transfer factors for various radionuclides began with the 1962 edition of the UNSCEAR (United Nations) reports already cited. Each new edition brought summaries of work done all over the world. In a 1980 document, we find an equation for evaluation of the transfer factor for ^{90}Sr in each individual component of the diet. The quantities are expressed as they appear in the UNSCEAR document:

The transfer from deposition to diet is quantitatively described by means of the transfer factor P_{23} , defined as the time-integrated $^{90}\text{Sr}/\text{Ca}$ quotient in the diet divided by the ^{90}Sr integrated deposition density. The integrals may be replaced by summations if the relevant quantities are assessed over discrete intervals of time. In fact, annual values are the most generally available information. The transfer factor P_{23} is usually expressed in mBq y/gCa per Bq m^{-2} .

The transfer factor may also be evaluated for each individual component j of the diet p_{23}^j . Expressing the fractional contribution of component j of the diet to the total dietary calcium intake as W_j , the transfer factor for total diet is

$$P_{23} = \sum W_j p_{23}^j$$

The transfer to diet from a specific deposition occurs over an extended period as long as ^{90}Sr remains in soil available for root uptake. Several models have been used to predict the ^{90}Sr levels in diet from data on past deposition densities. The model which appears at present to be most adequate for expressing the transfer of ^{90}Sr from deposition to diet is

$$C(n) = b_1 f(n) + b_2 f(n-1) + b_3 \sum_{m=1}^{\infty} f(n-m) e^{-\mu m}$$

where $C(n)$ is the $^{90}\text{Sr}/\text{Ca}$ quotient in total diet, in a food group, or in an individual food item, in the year n ; $f(n)$ is the annual deposition density in the year n , and b_1 , b_2 , b_3 , and μ are factors which can be derived from reported data by regression analysis. The factor b_1 represents the contribution to dietary ^{90}Sr per unit deposition density in the current year, while the factor b_2 expresses separately the contribution in the previous year, reflecting also the use in the current year of stored food produced in the previous year. The sum in the third term expresses the contribution to dietary ^{90}Sr from the deposition density in all previous years, resulting from root uptake and taking into account decay and loss of availability due to downward movement in soil or to other physical or chemical changes which may occur. The inverse of μ is the mean life of available ^{90}Sr in soil, which varies for individual foods and soil conditions.

The transfer factors for individual food types are in reasonable agreement for milk products in all three areas, and for vegetables, fruit, and grain products, in New York and Denmark. Differences are due to different definition of food groups and also different soil conditions and agricultural practices in the three countries. The parameters for the Argentine diet are probably more uncertain, mainly because the deposition density rate did not peak as sharply in the southern hemisphere, resulting in a decreased discrimination power of the regression analysis.

The contribution from each food group to total dietary calcium intakes, W_j , vary from country to country due to different consumption habits. To compare relative contributions to the total diet transfer factor P_{23} , it is necessary to compare the product $W_j p_{23}^j$. In New York the contribution to total dietary $^{90}\text{Sr}/\text{Ca}$ quotients is approximately equal from three food groups: vegetables 28%, milk products 27% and fruit 26%. In Denmark the greatest contributors are grain products 46%, milk products 28% and vegetables 18%. Meat is a minor contributor in both countries. In Argentina the contributions are grain products 39%, milk products 38%, fruit and all vegetables 13%, and meat 10%. (UNSCEAR 1980)

The parameters found for New York, Denmark, and Argentina are shown in table 15.5.

This may be more than many readers wish to know about transfer factors for a given element, but it shows what can be done from the research efforts mounted over many years.

TABLE 15.5. Parameters of the Transfer Function for ^{90}Sr Between Deposition Density and Diet (regression fits through 1976 data from New York, Denmark, and Argentina). [See text for definition of terms.]

Parameter a/	Milk Products	Vegetables b/	Fruits c/	Grain Products	Meat Fish Eggs d/	Total Diet
— New York —						
b_1	0.69	0.96	1.37	0.88	0.003	0.91
b_2	0.23	0.38	0	1.88	0.22	0.58

a/ The unit for parameters b_1 , b_2 , b_3 is mBq y (gCa)^{-1} per Bq m^{-2} . The unit for parameter μ is y^{-1} . The unit for the transfer factor P_{23} is mBq y (gCa)^{-1} per Bq m^{-2} . W_j is the fractional contribution of component j to the total Ca in diet.

b/ Values given in this column for Argentina include fruits and vegetables.

c/ Values given in this column for Argentina are for root vegetables.

d/ Values given in this column for Argentina are for miscellaneous food.

Source: Modified slightly and reset from UNSCEAR 1980.

An area of indirect but important bearing on biomedical problems is the effect of soil chemistry on the movement and complexing of strontium. A large amount of work has been done in this area, much of it in the USSR and much of it in the 1950s. The field involved scientists from many laboratories and included some of the experimental work described in chapter 13. Nevertheless, much of it did not involve the internal emitter establishment as described in this book. C. W. Francis (1978), a member of the Environmental Sciences Division at ORNL, has produced a comprehensive and critical review of the movement of radio-strontium in soils and its uptake by plants. It includes as much as possible of the Russian work, which appears to be responsible for well over half of the

research findings described. An overview of the subjects covered can be gleaned from a list of the chapter headings.

1. Distribution of Fallout Strontium-90 in Soil Profiles
2. Movement of Radiostrontium in Soils
3. Strontium Soil Reaction Products
4. Plant Uptake of Strontium from Nutrient Solutions
5. Strontium Uptake by Plants as Influenced by Soil Properties
6. Soil Amendments Affecting Radiostrontium Uptake by Plants

The research leaves little doubt that, while strontium is not strongly complexed to soil constituents, differences in soil chemistry can, as expected, greatly influence its availability for transfer and its uptake by plants. Quite surprising was the fact that liming, i.e., addition of calcium, was useful in reducing the uptake of strontium by plants only when they were growing on acid-base-unsaturated soils. With pH above 6.2 and base saturation above 75%, liming was not a practical method for reducing strontium uptake. The largest effect was seen with the addition of phosphorus, and this was most effective with tropical-type soils or neutral or alkaline soils. Work in both the United States and the USSR showed that applications of large amounts of phosphate fertilizer, plus liming, did, indeed, reduce radiostrontium uptake from contaminated soils. Unfortunately, the quantities required exceeded twenty metric tons per hectare, not economically feasible except under exceptional conditions.

2. Cesium

a. General

Movement of cesium isotopes in the environment was studied zealously, and in depth, from the beginning of the contamination episodes, especially fallout from weapons tests. We saw earlier (chapter 13) that cesium is bound tightly to many components of soil and that this can influence uptake into biota.^(a) Yet, as we saw in chapter 12, cesium isotopes are fairly homogeneously distributed in organisms. It follows potassium in its metabolism and accumulates in soft tissues, very little in bone in contrast to strontium. In nuclear fission, the radioisotopes of cesium are of considerable importance since they appear in high yield, and the most important isotope, ¹³⁷Cs, has a moderately long radioactive half-life (30 yr). By contrast, it has a relatively short biological half-life, 74 to 180 days in different organisms.^(b) There can be much turnover and recycling of cesium in the environment and in biota. Thus, the environmental transfer phenomena for cesium are quite different from those for strontium.

Since cesium has a short biological half-life in contrast to the long retention in bone of strontium isotopes, there was no equivalent of the "Sunshine Project" for cesium and, in a sense, it was eclipsed in the early work by strontium. Yet most of the same laboratories and workers were involved in the investigation of cesium as we met earlier for strontium. When it was apparent that the sources of radiocesium were continuously renewed during the era of atmospheric testing, the level of work grew apace. Indeed, some of the highest doses to humans from global fallout have occurred from cesium in the arctic

(a) For additional evidence, see Cummings et al. (1969) in work at the Southeastern Radiological Health Laboratory.

(b) National Academy of Sciences-National Research Council report to Federal Radiation Council, December 1964, cited in chapter 12. Children can be less by factors of three.

food chain (see below). There was also ample evidence of recycling of cesium in areas contaminated by radioactive waste.

Transfer of cesium to the diet is normally quite high for the first few years after deposit. It becomes low if the source has dwindled to largely the complexes in soil. However, in many situations this does not occur. Wallace, Romney, and Wood (1971), from the University of California, Los Angeles (UCLA), studied stable cesium circulation in the desert ecosystems of NTS. They found that, while the rates were low, circulation was definitely occurring and continuing. The compartments studied were soil, several plant species, arthropods, reptiles, and mammals. There was a progressive narrowing of the potassium/cesium ratio from plants to reptiles to mammals.

In other work from UCLA, Romney et al. (1971) investigated areas of "old" fallout over a period of several years. Transfer from abiotic to biotic components of the environment was continuing from shots in 1953, 1955, and 1957 to the latest time of study (about 1966–1970 for this publication). There was a decrease in the role of the inhalation route as the amounts of radioactivity available for resuspension by wind gradually fell, but ^{137}Cs continued to move through the gastrointestinal tract of jack rabbits and kangaroo rats. The amounts were not large, but sufficient to indicate continual recycling of the nuclide.

Perhaps the longest study period, thirty years, involved the White Oak-Lake flood plain at Oak Ridge. Dahlman and Van Voris (1976) went back over an area contaminated since 1944. Practically all of the ^{137}Cs soil was still within 60 cm of the surface. Relative concentrations were 0.6 for root/soil, 0.03 for above-ground vegetation/soil, and 0.04 for above-ground vegetation/roots. Furthermore, the distribution between plants and soil was the same at the time of this study as it was fifteen years earlier in 1959, i.e. about 0.03. This may be one of the most steady steady-states in radioecology.

As we have already seen, much work was done to ascertain the movement of cesium in food chains. While there is an ample amount in milk, grain products and meat provide about half of the ^{137}Cs intake (UNSCEAR 1972, p. 52), and the amount in milk is strongly dependent on deposition rates.

In general, the researches on cesium have not indicated the consistent discrimination at each step in the transfer process that we saw for strontium (chapters 12 and 13). Yet, workers at the University of Utah studied the cesium/potassium ratio in many animal species and found that it was two to three times higher in the organism than in their normal diets (Pendleton et al. 1965). It was a function of the potassium intake and of age. Thus, there was some concentration with trophic level increases.

Other research bearing on ascertaining transfer factors included the many studies on ^{137}Cs body burdens in humans measured by whole-body counting. In addition to the several studies quoted in earlier connections, a PHS survey of children in Florida and Illinois, done in 1969, should be added (Karches et al. 1969), as well as later research in Utah correlating ^{137}Cs body burden with milk content (Lloyd et al. 1973). The latter work went back to the nineteen dairy farms utilized in the 1962 to 1966 fallout studies (chapter 12) and the testing of a model. They conclude that prospective or retrospective projection of human cesium body burdens may be made from estimates of milk content.

An interesting set of studies on radionuclides in the diet of adults in Chicago was carried on by Gustafson at Argonne National Laboratory (ANL). It resulted in several reports, examples of which we have already seen in other connections. In 1970, Gustafson showed how the content of ^{137}Cs in the diet could lag

the deposition. The maximum in diet occurred about a year later than the maximum in deposition. The amount in diet held up even though deposition decreased markedly. This could be presumed to reflect the recycling phenomena we have discussed.

A sample of the data is shown as figure 15.9.(a)

FIGURE 15.9. Annual average ^{137}Cs deposition in the midwestern United States, and annual average ^{137}Cs level in the Chicago adult diet. (Redrawn from Gustafson et al. via NCRP 1977. [The ordinate units for deposition are mCi/km^2 , for diet pCi/gK .] Reprinted with permission of the National Council on Radiation Protection and Measurements, Bethesda, Maryland, copyright 1977.)

The facts above and recent events such as the Chernobyl reactor accident (chapter 21) suggest that we should probably have designated cesium as a "critical" radionuclide, along with strontium, in considering fallout. The short biological half-life led the thinking astray, since the phenomena of recycling were not factored in for the early computation. We are still learning!

b. Cesium in the Arctic and Subarctic—A Special Case

In earlier connections, we have described briefly the fact that the very short food chain of lichen-caribou (or reindeer)-man in arctic and subarctic environments changed the relationships characteristic of temperate climates. Details are well traced in the book by Whicker and Schultz already cited (vol. 1, p. 173 et seq.). It appears that one of the earliest clues came from work of a Professor Lidén at Lund, Sweden, who found significantly higher body burdens of ^{137}Cs in Scandinavians who had eaten significant quantities of reindeer meat than in others (Lidén 1961). This was in 1960–1961. Two reindeer-raising Laplanders had as much as thirty to forty-five times as much ^{137}Cs as individuals from Lund. In 1962, Hanson, from Hanford, found ^{137}Cs burdens in Alaskan Eskimos comparable to those in the Laplanders. By the time of the Stockholm symposium on radioecological concentration processes, the subject was under intensive study in Alaska (Hanson, Watson, and Perkins 1967), in Sweden (Lidén and Gustafsson 1967), in the USSR (Nevstrueva et al. 1967), in Finland (Miettinen 1969a,b), and in Norway (Hvinden and Lillegraven 1961).

(a) This is from the work of Gustafson at ANL, but taken from a summary report on cesium from the environment to man prepared by Scientific Committee-23 of the NCRP (NCRP 1977). This report provides a succinct summary on environmental ^{137}Cs , with particular emphasis on dosimetry.

Even though the populations were relatively small, a significant number of individuals were studied. Some Alaskan Eskimos reached, and even maintained, body contents that delivered from three to four times the annual radiation dose attributed to natural background, taken as 150 mrad. This was much more than normal population standards would permit. Since the doses were the result of nuclear weapons testing, and there was talk of Plowshare events in Alaska, intensive efforts from U.S. laboratories^(a) went into studying the subject (see also chapter 12).

The Hanford group worked on the North Slope in Alaska (Hanson 1967), a group from Canada looked at subarctic Canada (Bird et al. 1965), and the Miettinen group from Finland looked further at Finnish Laplanders (Miettinen and Häsänen 1967). Like the Hanford group in Alaska, the Finns toted whole-body counters to remote villages (their use was possible because of the relative ease of measuring ^{137}Cs), and they measured both the populations (Miettinen 1969b) and the flora (lichens) and fauna (caribou and reindeer). They also sometimes brought the people to the laboratories for measurement.

This international effort showed consistently that the cesium in Alaskan Eskimos and Finnish Laplanders and other inhabitants of the subarctic was as much as a factor of one hundred above that in people in the north temperate latitudes. Other radionuclides, including "natural elements" such as ^{210}Pb and ^{210}Po , behaved in the same manner as was found by Persson (1967) from Sweden and by the Finns (Kauranen and Miettinen 1967). Indeed, ^{210}Po also reached quite high levels (see chapter 4).

The difference lies, of course, in two peculiarities of transfer factors in the arctic and subarctic environment: (1) lichens cover a large part of the surface area, and their surface structure holds any deposited radionuclide tenaciously (half-life as high as seven hundred days, even ten years); also lichens are very long-lived; and (2) the diet of a typical Lapp may average 70% to 90% reindeer or caribou meat. That meat had received ^{137}Cs in a mobile form directly from the lichens. There was little interposition of soil-forage-milk pathways and the like. There were, of course, seasonal variations because of seasonal changes in diet.

In retrospect, it may seem that an inordinate amount of effort went into this work. The reasons and the mechanisms seem fairly obvious and not at all surprising. However, we must remember that this was during the peak of the fall-out polemics. There were U.S. citizens and world citizens carrying body burdens above those considered allowable by the current recommendations of the Federal Radiation Council for individuals in the population or for populations (1,000 nCi).^(b) The testing was still under way at the beginning of the work. How much higher would these levels go? Was this a prologue to further increases in temperate latitudes? There was much concern, some of it conscientious and justified; some of it unwarranted, since the fact that this was a very unusual food chain with unusually high transfer factors was forgotten or lost sight of.

(a) A large portion of the published work from the United States for the earlier years came from Hanford. They actually began in 1959. In later years, the Lawrence Livermore group began a somewhat more wide-ranging survey that encompassed many isotopes in addition to ^{137}Cs . However, the Arctic story is primarily a cesium story. A listing of some of the Hanford and UCRL reports on this subject is given as note 2 at the end of this chapter.

(b) Amounts measured were not greatly higher, e.g., 1,280 nCi; 1,620 nCi; 3,000 nCi; etc.

It can be concluded without doubt, however, that short food chains with high transfer factors can be dangerous and perhaps produce unexpected surprises. These phenomena in the Arctic strengthen further the conclusion that cesium should have been designated as a critical "radionuclide."

3. Iodine

a. General

In earlier chapters, we considered the development of ideas concerning iodine releases from nuclear reactors and from chemical processing plants, and the large enterprise that surrounded iodine in fallout. We saw that it was iodine in the environment that probably first focused attention on the importance of food contamination from fallout. We reviewed in some detail the work done in Utah and Nevada regarding milk contamination from the Nevada tests and the generalized milk networks set up around global fallout. We also traced the gradual shift in emphasis from thinking of iodine as primarily an inhalation hazard in occupational exposure or local releases to primary concern about its presence in milk and dairy products. Yet, there are some aspects of iodine transfer in the environment that need to be considered further before we can close the discussion. These aspects will be reviewed briefly in this section.

Appropriate to the fact that much of the work on iodine in the environment began at Hanford is the fact that Hanson wrote a succinct review on iodine for the First National Symposium on Radioecology, described in chapter 11 (Hanson 1963). This review included both stable and radioiodine in many media, the utilization of iodine by plants and animals; and the basis for transfer factors that could be used in later models. At the same symposium, French and Larson, from UCLA, discussed environmental pathways for iodine from nuclear tests in arid regions (French and Larson 1963). These and many others made it quite clear that the chemistry of iodine in reactors, in released clouds, and in the environment can be quite complex, but that surface adsorption can play a prominent role at the forage step. Evidence for a predominant role of ingestion came from two facts: (1) animals existing in a contaminated environment, but prevented from ingesting contaminated material, showed little or no radioiodine in their thyroids; and (2) thyroid radioiodine continues to increase for several days after a contaminating event, a course not expected after inhalation, but consistent with continuing ingestion.

Soldat (1963, 1965) added to insight into the passage of ^{131}I in food chains by measuring the kinetics of its behavior in various media, including air, pasture, milk, and cattle thyroids. The work was reported at the Hanford life sciences symposium on the biology of radioiodine in 1963. An average delay of about six days occurred between the peak in vegetation and appearance in milk, about twelve days between peak concentration in grass and in the cow's thyroid. (The British developed slightly shorter times from their investigations around Windscale.) Average ratios of several components needed to estimate transfer functions were developed:

$$\begin{array}{lll} \frac{\text{pc/kg of grass}}{\text{pc/m}^3 \text{ of air}} \approx 4,200 & \frac{\text{pc/g thyroid}}{\text{pc/kg grass}} \approx 0.45 & \frac{\text{pc/l milk}}{\text{pc/m}^3 \text{ air}} \approx 600 \\ \frac{\text{pc/l of milk}}{\text{pc/kg grass}} \approx 0.15 & \frac{\text{pc/g thyroid}}{\text{pc/l milk}} \approx 3.0 & \end{array}$$

Soldat also gave the ratio of doses to the thyroid from milk compared to air—20 for a 20-g thyroid and 400 for a 2-g thyroid.

The UNSCEAR 1972 report has much to say about the complexity and variability of the behavior of iodine in the environment. The amount of activity in the form of particles can vary from 10% to 90%, with the balance in gaseous form. Doses can be calculated only if *local* deposit and transfer patterns are known or if milk levels (fresh milk is the principal source among the foods) are known. Also, neither field nor laboratory techniques for measuring iodine separate from gross beta activity were available in the years of most feverish activity in measuring and characterizing fallout. Thus, for 1952, 1953, and 1957, integrated milk levels were derived from beta activities in air, as we saw in chapter 12.

As techniques advanced, specific models for iodine isotopes gradually emerged. A major development began in the 1960s at Idaho Falls that had a strong influence on these and on the allowable limits for iodine in the environment. We will review this in the next section.

b. The Controlled Environmental Radioiodine Tests at Idaho Falls^(a)

In chapter 14, we reviewed field exposures of animals to fission products from melted reactor fuel elements at the National Reactor Testing Station in Idaho. Iodine predominated in the releases from “green” fuel elements in these tests (called FPFRT for Fission Product Field Release Tests). At the time, we remarked that further special tests took place at Idaho Falls, but they were so intimately related to the analysis of transfer factors in the environment that we would postpone discussion to chapter 15. These were the Controlled Environmental Radioiodine Tests (CERT), whose stated objectives were:

1. to derive a mathematical model to predict the deposition and retention of radioiodine as a function of (a) vegetation type and state, (b) chemical and physical form of radioiodine, and (c) meteorological conditions
2. to derive a mathematical model to predict the transfer of radioiodine from vegetation to milk
3. to derive a mathematical model to predict the dose from radioiodine to humans.

It was determined that a very important transfer factor to be characterized was the “deposition velocity” (V_g) for ^{131}I from air to pasture grasses or vegetation. To assess it and other relationships for the air-vegetation-cow-milk-human food web, the Idaho Falls group decided to set up a series of tests with ^{131}I generators and a sample grid in areas of typical pasture grass. There were also some cows, kept in an experimental dairy farm, which could be fed the grass and even some human volunteers who placed themselves in the passing cloud of iodine vapor, or who drank milk from the cows and had their thyroid glands counted at the laboratory.

The first report (Hawley et al. 1964) was labeled “preliminary” but seems to have been quite complete. A total of 970 mCi of ^{131}I were released as a gas over a thirty-minute period onto a pasture of crested Wheatgrass. About 13% of the iodine deposited on the sampling grid and 1.5% on the grass. Deposition

(a) The author is greatly indebted to Dr. Eddie W. Chew, Chief Environmental Sciences Branch, Radiological and Environmental Sciences Laboratory, Idaho Operations Office, DOE, for copies of the pertinent IDO reports.

velocities were calculated as 0.4 to 0.8 cm/sec with an average of 0.6 cm/sec. Effective half-life on the grass was about 3.5 days, and the ratio of activity in milk (pCi/l) to that on the grass (pCi/g) was 240 ± 35 .^(a) The average human thyroid uptake of the ingested ^{131}I was 19% and the predicted dose to the thyroid 0.39 rad. It was a satisfactory test.

No further reports appeared for nearly two years. However, the tests continued in the interim, viz., September 1964, December 1964, May 1965, and June 1965. The schedule included two tests over open-range-type vegetation, two tests over irrigated pastures, and one over snow-covered ground. Meteorological conditions varied from lapse conditions (two tests), to inversion conditions (two tests), and neutral conditions (one test).

A report edited by Hawley (1966) gives progress through 1965 and summarizes the first five experiments. A sixth test, using methyl iodide, and a seventh designed to provide information on movement under late fall and early winter conditions were described in a report edited by Bunch (1966). A later report by Bunch (1968) gives a summary of the purposes of each test, the location of the release, etc. A copy of this summary of nineteen tests is given as table 15.6.

As time wore on, the cows and human thyroid steps were sometimes omitted to allow concentration on some of the more difficult steps at the front end of the chain. Mathematical models for bovine metabolism of ^{131}I ^(b) and other steps began to emerge, and these were compared to other models, such as that proposed by Garner (1967).

Further information was contained in a report by Zimbrick and Voillequé (1969) and in a paper presented by Pelletier and Zimbrick (1970) at the Health Physics Society Mid-Year Topical Symposium in Augusta, Georgia.

Along with the field work, it was found necessary to develop a laboratory experimental program (late in 1964) with objectives to isolate each variable more than could be done in the field, and to improve techniques. This program was dubbed "CERTLE."

Principal results as outlined in 1967, but actually not changed much in subsequent work, included the following:

1. No significant difference was observed in behavior of molecular iodine from a few hundred meters out to two miles from the release point.
2. Deposition velocity figures were usually below 1 cm/sec but varied with areal grass density.
3. A strong linear relationship existed between normalized deposition velocity and friction velocity under moderate wind speeds in an unstable atmosphere. It was not so strong with light winds and a stable atmosphere.
4. Deposition velocity for methyl iodide is on the order of 0.05% of that of molecular iodine.
5. The average uptake fraction in human thyroid from contaminated milk was 0.19.
6. The average uptake fraction in human thyroid by inhalation was 0.30 (three subjects, one release).
7. A reasonably satisfactory model for bovine metabolism of radioiodine was constructed.

(a) The units for this ratio are pCi/l of milk to pCi/g of grass, whereas those on page 1298 use pCi/kg grass. The ratios in common terms would be 0.16 versus 0.24 or 150 versus 240, depending on the units chosen and if the agreement between the studies is satisfactory.

(b) Interestingly, this included a compartment for radioiodine in body fluid not available for secretion in milk.

TABLE 15.6. Objectives of Specific CERT Tests

Test Number	Release Time	Date	Location	Test Objectives
1	1500	5/27/63	Atomic City Area	To check techniques and experimental design to be used in establishing three basic relationships under known natural release conditions: (1) The amount of radioiodine in the air relative to that in soil and vegetation. (2) The amount of radioiodine on the vegetation relative to that in milk. (3) The quantity of radioiodine in milk relative to that in the human thyroid after drinking the milk.
2	1344	9/2/64	Experimental Dairy Farm (EDF)	To determine the three relationships in Test 1 above using an irrigated pasture typical of present farming practices in this area.
3	1354	12/11/64	EDF	To obtain information on the meteorological aspects of iodine deposition using snow as the surface for deposition.
4	0430	5/27/65	South of SL-1	To measure the deposition velocity of I_2 on grass during stable atmospheric conditions.
5	0515	6/10/65	South of SL-1	Same as Test 4.
6	1400	9/14/65	ICPP Stack (Idaho Chemical Processing Plant)	To evaluate the behavior of CH_3I in the milk-food chain.
7	1410	11/22/65	EDF	To determine radioiodine behavior in late fall or winter.
8	2040	5/31/66	NE of ICPP	To check techniques and experimental design to be used in evaluating the deposition of radioiodine under various meteorological conditions.
9	0245	6/7/66	NE of ICPP	Same as Test 8.
10	1040	6/14/66	Test Grid 3	To determine the behavior of elemental iodine over travel distances typical of postulated reactor accidents.
11	1323, 1331	7/21/66	EDF	To evaluate the behavior of CH_3I in the milk-food chain.
12	2108	7/26/66	EDF	To measure the deposition of CH_3I at night.
13	1020	8/3/66	EDF	To measure the deposition of elemental iodine as a function of meteorological conditions.
14	0234	8/5/66	EDF	Same as Test 13.
15	0540	8/5/66	EDF	Same as Test 13.
16	0230	8/24/66	EDF	Same as Test 13.
17	0530	8/24/66	EDF	Same as Test 13.
18	1955	9/8/66	EDF	Same as Test 13.
19	1024	11/7/66	EDF	To evaluate the behavior of radioiodine in late fall.

Source: Reset from Bunch 1968.

In addition to the iodine tests, the Idaho Falls group did work with ^{137}Cs on a Michigan dairy farm (referenced in chapter 12), onsite at the National Reactor Testing Station, and more general radioecology and ecology programs.^(a) The significance and uses made of some of this work will become apparent in the next section.

c. The Factors of 700 and 1,000

In the work of Soldat' (1963) described above, we saw a factor of 600 between pCi/l of milk and pCi/m^3 of air. This, and similar figures from other sources (e.g., the fallout studies in Utah and other work on the iodine-milk pathway), led the regulators to considerable concern about the validity of the then-current maximum permissible air concentration $[(\text{MPC})_a]$ of iodine for population exposure. Table II, Appendix B of Title 20 of the Code of Federal Regulations (10 CFR 20) had set a "legal" $(\text{MPC})_a$ in the environment for ^{131}I of $1 \times 10^{-10} \mu\text{Ci/cc}$. The fact that such values did not take any account of the "reconcentrations"^(b) and food-cycling phenomena we have been examining disturbed the regulators. They had already urged that all releases be "As Low as Reasonably Achievable," but this did not seem to be enough.

In a new appendix (Appendix I)^(c) to Part 50 of the Code of Federal Regulations, which covered licensing of production and utilization facilities, some numbers were attached to the "As Low as Reasonably Achievable" recommendations. These were designated to apply specifically to the effluents from light-water-cooled reactors. This placed a limit on annual total body exposure of individuals in unrestricted areas of 5 mrem and a calculated annual total radiation dose or dose commitment from all radioactive iodine and radioactive material in particulate form in effluents released to the atmosphere of 15 mrem to any organ from all pathways. These were a factor of one thousand lower than the extant occupational whole-body limit of 5 rem/yr and individual organ doses of 15 rem/yr, respectively, then in effect. It is commonly understood that this factor represented a rounding off, upward of a factor of seven hundred derived from the environmental transport work, much of it in the CERT tests. The exact calculations are not given in any official derivation, but they were common corridor conversation at environmental and regulatory meetings of the day and were fortunately summarized for posterity by Burnett (1970) at Oak Ridge.

The 10 CFR 20 table II Appendix B limit for ^{131}I in population exposure, i.e., $1 \times 10^{-10} \mu\text{Ci/cc}$, can be compared to an air concentration limit derived from use of a deposition rate of 1 cm/sec and other transfer factors in the milk pathway of $1.42 \times 10^{-13} \mu\text{Ci/cc}$. Conversely, we can take the Part 20 figure and divide it by the effective renewal constant and get an allowable concentration on vegetation of $0.625 \mu\text{Ci/m}^2$ if there were no environmental cycling. The figure with recycling using the numbers derived by the Federal Radiation Council (FRC 1964) (80 pCi per day and drinking 1 l of milk per day) was $8.9 \times 10^{-4} \mu\text{Ci/m}^2$. The ratio of these is about 700 in each case ($1 \times 10^{-10}/1.42 \times 10^{-13}$ and $0.625/8.9 \times 10^{-4}$). This ratio came from the iodine figures; it could have been derived in other ways also. If we add the smaller contribution of other radionuclides in the

(a) Bibliographies are available in Reports IDO-12078 (November 1973) and DOE/ID12098 (June 1983).

(b) The term is put in quotes since, while it is the one commonly used, it is not accurate. "Recycling" or simply cycling leading to increase in concentration is the process.

(c) Capital I, not the number one.

environment and the usual rounding off for safety, the factor of 1,000 is understandable. What is not so understandable is that this is still applied primarily to light-water-cooled reactors. They are not the only potential sources of iodine or other pollutants in the environment.

There were some later reassessments of the reduction factor for food chains, which were aimed especially at the deposition velocity figures. George (1970), who worked at the Sterling Forest (New York) Research Center of the Union Carbide Corporation, calculated that the thyroid dose for a six-month-old child by the direct inhalation pathway (at the ICRP limiting air concentration of 10^{-10} $\mu\text{Ci/cc}$) was 2.56 rem/yr. By contrast, the dose from the same air concentration and using 0.091 $\mu\text{Ci/l}$ per $\mu\text{Ci/m}^2$ as the milk-to-grass ratio and 1 cm/sec as the deposition velocity came out to 224 rem/yr. This was only a factor of 88 above the direct inhalation route. However, George does not object to the limits set in Appendix I. He cites the variability in some of the factors, e.g., the ratio of amount in milk to that in grass and in the deposition factor. Using different input values, he calculates a "reconcentration factor" of 200. Thus, use of the Appendix I dose limits may include a larger safety factor than stated above. George concludes, "The 700 factor is thus simply a number by which the $(\text{MPC})_a$ should be reduced when considering the milk exposure route."

Hoffman (1977), from Oak Ridge, contended that the environmental transport factor for air to pasture was underestimated in the earlier calculations because the measurements involved only the vegetation cut above a square meter of ground surface. This neglected the amounts deposited on detritus, root mats, and soil, while the calculation is for total deposit on a unit area of pasture. To account for this, he suggests use of two factors, V_g for total deposition velocity and V_D for vegetation only. He tabulates a large number of deposition velocities and other factors for the air-to-milk transport of ^{131}I and reviews the several assessment models done in various laboratories: Bayer (1972); Bryant (1964); Fletcher and Dotson (1971a); Hoffman (1973); Palms, Veluri, and Boone (1975); Soldat (1976); EPA (1973); AEC (1974a); and WASH-1400 (NRC 1975). The V_g values do indeed vary as seen in the CERT tests. The milk-to-air ratios resulting therefrom for ^{131}I varied from 190 to 5,400, with an average of 800.

Hoffman points out that the variations in milk-to-air ratios cannot be considered as errors. The physicochemical form of the iodine might have been truly different. The physicochemical form, including particle size, can move the available fraction of deposited radionuclide over a wide range, and we know this does vary. Indeed, he calculates a milk-to-air ratio for elemental iodine of approximately 6,000 (Ci/l per Ci/m^3) but points out that the value for small particle sizes may be only 300 or, for methyl iodide, only 30.

Hoffman,^(a) like George, does not suggest that the current standards should be changed, but urges more attention be paid in new work to the physicochemical form of the iodine in air so that future predictions can be made with fewer questions.

In 1978, another review appeared, also by Hoffman (Hoffman 1978), that concerned the values used for the transfer of iodine from diet to milk. His review led to recommendation of values slightly higher than those recommended in the NRC Regulatory Guide 1.109. The difference is again in the direction of more transfer than in the "legal" figures.

(a) A broad discussion of uncertainties in radiological assessment models can be seen in the chapter by Hoffman and Gardner (1983) in a book edited by Till and Meyer (1983).

Whether or not these modifications will lead to changes in regulatory position must await the publication of the revised Code of Federal Regulations. It is clear that, despite CERT and the variety of modeling work done, things are not yet cut and dried for the iodine-to-milk pathway.^(a)

4. Plutonium and the Transplutonic Elements, with Notes on Uranium and Thorium

We have seen (chapter 11) that plutonium is, in general, a markedly insoluble element.^(b) The other actinide elements, e.g., americium, curium and neptunium are somewhat more mobile, especially neptunium. Nevertheless, as a class, the actinides would not be expected to show transfer in the environment comparable to the other elements singled out for discussion above. Yet, there is a very large literature, and it is still growing, on transplutonic elements in the environment. We have already referred to the Gatlinburg symposium of the Nevada Applied Ecology Group (NAEG) (White and Dunaway 1977) and the IAEA symposium at San Francisco on transuranium nuclides in the environment (IAEA 1976). The Department of Energy got together several other symposia and sponsored the well-known and authoritative summary of environmental research on transuranium radionuclides edited by Hanson (1980). These are but a sample. Even more recent additions are a succinct summary by Watters (1981), given at the Snowbird symposium on actinides (Wrenn 1981a), and a short discussion by Kathren (1984) in his book on radioactivity in the environment. The locales for the work are largely the already familiar ones, PNL (Hanford), UCLA, the NAEG (chapter 14), Colorado State University, Lawrence Berkeley Laboratories, and the University of Utah and others for the more recent forays into environmental aspects of actinides.

Why should so much effort have been expended on a relatively insoluble group of elements? One obvious answer is the very long half-lives of many of these radionuclides. Another is their continuing presence in radioactive wastes. Another is the stimulus of the proposed "plutonium economy" associated with plans for a fast breeder reactor, a stimulus that has recently faded markedly in the United States, but is still important in other parts of the world. Another is the finding, described in earlier chapters, indicating that plutonium may be solubilized in the environment with time and become more mobile. And finally, there is the vaunted high toxicity^(c) of plutonium and general fear of the presence of

(a) We have had to neglect contributions from abroad, except for our earlier reference to Windscale. One is directly pertinent to the present discussion and should be noted. Heinemann and Vogt (1980), working at the Julich Nuclear Research Center in West Germany, measured deposition velocities of iodine in field experiments. The average deposition velocity was estimated at 2 cm/sec, somewhat higher than the figure used in U.S. calculations. Furthermore, they found that it was still greater on moist surfaces and, since there is more moisture in general at Julich than at Idaho Falls, they proposed using a factor of 3 cm/sec for the Federal Republic of Germany. On the other hand, they found deposition for aerosols to be lower by a factor of twenty and methyl iodide to be only 0.5% of that of elemental iodine.

(b) Concentration ratios in terrestrial systems are on the order of 10^{-3} to 10^{-6} but considerably higher in aquatic systems because of uptake by organisms like phytoplankton.

(c) Remember in chapter 8 we negated some of the claims that plutonium is "the most toxic element known to man."

even one atom of plutonium in the environment. In the presence of such fear, every laboratory bent over backwards to get all possible information.

This was not always so. In the early years, plutonium and the actinides were viewed as primarily inhalation hazards, and the venue was occupational rather than population exposures. This was strengthened by the demonstrations of high carcinogenic potential for plutonium in the lung (chapter 9). Indeed, even the early considerations of plutonium in fallout looked first at its potential as an inhalation hazard. This gradually changed as the environmental groups turned from fission products to plutonium and the other actinides. We find in the early seventies expressions of dismay that plutonium uptake and transfer in nature had been neglected in both aquatic environments (Noshkin 1972) and in terrestrial environments (Romney and Davis 1972) such as those around Hanford, Rocky Flats, NTS, the Trinity site, and others. It did, indeed, become apparent that the actinides moved through the environment, although the movement was slow and in very modest concentrations compared to the fission products. Soon there began to be assessments of potential health effects of the actinides through hundreds of human generations, e.g., Barr (1974). The inhalation pathway was still prime for early exposures, but ingestion became of importance as time progressed. This is shown in figure 15.10, taken from Barr.

FIGURE 15.10. Summary of major routes to man. The expression "MWe-yr" means megawatts electrical energy each year. (Redrawn from Barr 1974.)

Note that the increased significance of ingestion may require hundreds or even thousands of years to take over from inhalation.^(a) Also, because of greater absorption from the gastrointestinal tract, nuclides other than plutonium (e.g., ^{241}Am , ^{237}Np) may become the largest contributors to dose.

Considerable interest has been attached for many years to areas with high levels of naturally-occurring radionuclides, principally near the surface. Much work has been done to determine, if possible, any ecological or population effects of the high external radiation dose associated with these. Two areas have been studied in most detail, one in India, the other in Brazil. The one in Brazil has contributed information of great interest to the problem of radionuclide transfer in the environment and of radioactive waste disposal.

Eisenbud has worked for many years with Brazilian colleagues to study the translocation of thorium and rare earth elements from a rich deposit in the state of Minas Gerais, Brazil. The results indicate almost total immobility for these isotopes. Let us see by quoting the abstract from a recent paper by Eisenbud and several colleagues (Eisenbud et al. 1984):

A highly weathered deposit of thorium and rare earth elements located near the summit of a hill in the state of Minas Gerais, Brazil, is being studied as an analogue for a radioactive waste repository that sometime in the distant future may be eroded to the surface or intruded by groundwater. Thorium serves as an analogue for Pu^{4+} , La^{3+} as an analogue for Cm^{3+} and Am^{3+} . The mobilization rate constants of the analogue elements by groundwater are so slow (of the order of 10^{-9} per year) as to suggest that essentially complete radioactive decay of the transuranic actinides would occur in place even under the relatively unfavorable conditions that exist at a site such as this.

These conclusions were expanded and strengthened by an erudite and convincing summary given by Eisenbud at a recent annual meeting of the NCRP (Eisenbud, Linsalata, and Franca 1985). If these phenomena can indeed apply to plutonium and related actinides, there should be a significant impact on waste considerations.

Details of radioecology studies on transuranics in the environment can be followed easily in the very useful review chapter by Watters et al. (1980) at the beginning of the book edited by Hanson (1980) and in the Snowbird actinide symposium (Watters 1981); also in the proceedings of the ERDA workshop at Seattle, cited in an earlier connection (ERDA 1976), and in briefer form in the book by Kathren (1984). In the chapter in Hanson (1980) there is a review of solubility and chemistry of plutonium and other actinides using data originating in a variety of laboratories for both aquatic and terrestrial systems, behavior in freshwater and marine environments, including the role of phytoplankton, the transfer in dust and soil, including the phenomena of resuspension, to be reviewed presently, and prediction of long-term behavior. Also, Durbin prepared a chemically oriented review of the transfer of plutonium to plants from soil that brought together data from many sources (Durbin 1974). The sources of data for these works include some old friends, U Pond at Hanford, White Oak Lake at Oak Ridge, several ponds and reservoirs at Rocky Flats. There are also

(a) Let us not neglect inhalation because of the realization that other pathways may play a part someday. One needs only to review the data presented by Bair (1974) at the same symposium as the Barr calculations to be convinced again of the potency of plutonium as a pulmonary carcinogen.

some new sources, e.g., canals, ponds, and the Miami River at Miamisburg, Ohio (Mound Laboratory); the Great Lakes; the Hudson River; the Savannah River; several Canadian lakes; and some ponds and lakes in the southeastern United States, to name a few.

There are complexities of detail. Concentration factors obtained in laboratory studies (chapter 13 and Price 1973) were one to two orders of magnitude lower than those found in field studies, both at Oak Ridge and NTS. A typical example taken from the work at UCLA and at NTS is shown as table 15.7. In each case, an increase in mobility with time appeared in the field work.

TABLE 15.7. Comparison of Plutonium Concentration Ratios for Field and Glasshouse Conditions

Soil Source	Field	Glasshouse
NTS Area 11B	1.3×10^{-2} to 1.6×10^{-1}	1.5×10^{-4}
NTS Area 11C	4.5×10^{-2} to 3.4×10^{-1}	1.8×10^{-4}
NTS Area 13	7.8×10^{-2} to 4.4×10^{-1}	1.1×10^{-4}

NTS (Nevada Test Site).

Higher concentration ratios for plutonium, e.g., 10^{-3} to 10^{-4} , were found in the arctic tundra system discussed above in connection with cesium (Hanson 1980). Two relatively recent reports show both the present status and the development of information on alpha emitters in the Arctic. One is from Finland (Jaakkola et al. 1981), supported by DOE. The other is from the University of Lund, Sweden (Holm and Persson 1981). However, before we get too excited about plutonium and the actinides in Arctic systems, we should compare them with the naturally occurring activity concentrations of ^{210}Po in the lichens. The data are shown as table 15.8. Obviously, ^{210}Po is the predominant alpha-emitting radionuclide in this system!

Both field and laboratory experiments showed marked differences among the actinides. For uptake by terrestrial plants, the order of uptake was $\text{Np} > \text{Cm} > \text{Am} > \text{Pu}$ (Price 1972; Schreckhise and Cline 1980; Kathren 1984). Neptunium could be from 2,200 to 45,000 times as mobile as plutonium (Kathren 1984).

Because of an increase in the recommended absorption factor (ICRP) for neptunium from the gastrointestinal tract, ^{237}Np became theoretically the controlling nuclide in high-level waste after several thousand years. The validity of this development has been questioned and is being examined in depth, particularly by Maurice Sullivan and Roy Thompson at PNL and the group at ANL through a task group of the NCRP (see review by Thompson 1982a).

Other members of the actinide group, such as uranium and thorium, have been cast in a different light. There is already an ample quantity of these in the earth's crust, and they are uniformly present in natural ecosystems. Because of their long half-lives and low level of radioactivity, they have not been considered as seriously, as environmental contaminants, as the elements mentioned above. Yet, as we will discuss presently, there is now considerable interest in

TABLE 15.8. Alpha-Emitting Nuclides in the Lichen *Cl. Alpestris*. (The values are representative for 1972.)

Nuclide	Activity Concentration	
	(pCi/kg dry weight)	Bq/kg dry weight
²¹⁰ Po	7000 ± 1000	260
²³⁴ U	5.6 ± 1.1	0.2
²³⁵ U	0.2 ± 0.1	0.007
²³⁸ U	5.4 ± 1.0	0.2
²²⁸ Th	3.4 ± 0.6	0.13
²³⁰ Th	1.9 ± 0.4	0.06
²³² Th	1.7 ± 0.3	0.06
²³⁸ Pu	6.3 ± 0.5	0.23
²³⁹⁺²⁴⁰ Pu	140 ± 10	5.2
²⁴¹ Am	30 ± 3	1.1
²³⁷ Np	0.4 ± 0.1	0.01
²⁴² Cm	0.006 ± 0.002	0.0002

standards for uranium in drinking water (Wrenn 1984; EPA 1981a,b), and its movement in the environment has been taken up in several laboratories in the United States.

In general, uranium is considerably more soluble than plutonium.^(a) A concentration factor of unity is usually assumed for it (Kathren 1984). Thorium compounds tend to be much less soluble than uranium salts.

Finally, it should be mentioned that metabolic modeling for the actinides has begun in earnest. For many years, we had only a model for uranium developed by Struxness et al. (1956) for the first Atoms for Peace Conference and reviewed by Durbin and Wrenn (1975) at the Arlington, Virginia, conference on uranium. There was reluctance to attempt much for the higher actinides. After all, the blue ribbon task group of ICRP that prepared Publication 19 on plutonium (ICRP 1972) could not establish a general metabolic model for the actinides in bone, even though the group working on alkaline earth metabolism could present a detailed model in ICRP Publication 20 (ICRP 1973, the "Marshall model").

In the late 1970s, various groups, particularly the one at the University of Utah, seemed to feel it was time to attempt some general metabolic modeling for the actinides, including models that would tie into environmental transfer. Accordingly, at the Actinide Workshop at Snowbird, Utah (Wrenn 1981a), a full session was devoted to actinide modeling. It contained a comparison of the metabolism of plutonium in dog and rat by Mahaffey and the group at PNL^(b) (Mahaffey et al. 1981); an in-depth discussion of retention factors, with a brief

(a) Remember the problem of leakage of uranium and other radionuclides from uranium mill tailings described in chapter 11?

(b) They also related the differences in metabolism to the incidence of tumors.

discussion of those for the actinides by Skrabble, Chabot, and Johnson (1981) from the University of Lowell; an URN-model^(a) approach to actinide metabolism by Bernard (1981) at Oak Ridge; and a more conventional mathematical model developed by Cuddihy (1981) at Lovelace. Some of the models are so complex that combining them with an environmental transport model seems almost impossible. Yet, although no one felt the ultimate model was yet ready, there was general optimism that progress was being made.

Wrenn and Durbin, at Utah and Berkeley, have been working on a revised metabolic model for uranium that could be appropriate for environmental intakes;^(b) they have published or presented at meetings its general development (Wrenn, Lo Sasso, and Durbin 1977; Wrenn 1981b; Roswell and Wrenn 1980; Wrenn and Roswell 1980; Durbin 1986). The principal change from earlier models such as those promulgated by the ICRP and NCRP resides in the factor for uptake from the gut. As already noted, and to be seen later in this chapter in connection with the setting of standards for surface contamination, a new metabolic model for uranium would be very timely.

Although models for the transfer of transuranics in the environment may have had a slower start than many other environmental contaminants, there is ample information now. Also, it has the honor of projecting further into the future than any other environmental transport system and a certain aura of mystery that accompanies calculations extending for thousands of years into the future.

There is much yet to be done, however. Watters (1981) outlined at the Snowbird meeting four lines of investigation needing attention:

1. more information on neptunium, americium, and curium
2. determination of the chemical species (presumably the predominant one) in the environment and kinetics of their formation
3. more information for the ingestion route and thus more ingestion experiments
4. models for environmental mobilization and transport (Yes, more models!).

There has, of course, been considerable interest in environmental transport of plutonium in laboratories in other parts of the world. We have had to by-pass most of the work since the results are not qualitatively different from those we have been discussing.

G. Miscellany Regarding Food and Water

Before we close out even this all-too-brief description of the genesis of the environmental transport systems, there are dilemmas and contributions that did not fit the categories chosen for use above that should be discussed.

The enormous efforts of federal and other governmental and private agencies in operation of the surveillance networks for measuring fallout in the environment, especially foods and water, were fundamental to all that followed. (See, for example, Federal Radiation Council [FRC] reports in chapter 12.)

(a) Derived from the concept of a container holding different colored balls to represent different atoms in an organ and application of statistical theory to the taking of samples therefrom.

(b) That is, for the absorption factors and other constants that would be consistent with the differences in solubility, etc., sometimes seen after passage through the environment and that could be keyed to the very low concentrations involved.

In many ways, we can be glad that the methodology for measurements of isotopes in animal and plant nutrition had already gotten a good start through tracer chemistry applications before the fallout dimension came on the scene. An example is the summer symposium held at Oak Ridge in 1952, entitled "The Role of Atomic Energy in Agricultural Research" (Comar and Hood 1953). The thrust of this symposium was the uses of isotopes in animal and plant nutrition research and tracer studies of soils and fertilizers. The isotopes were, of course, not those of later interest. They were radioisotopes of normal metabolites like ^{14}C and ^{32}P . Yet, the methodology learned set the stage for the later studies on food and food chains. In it, Comar (1953), just starting his work with the University of Tennessee-AEC Agricultural Research Program in Oak Ridge (see chapter 13), gives basic information on how isotopes can be used for many purposes in agriculture. These included direct movement in environmental media, movement into and within an organism (including incorporation into the organism), measurement of rates of movement, and precautions in the use of isotope methodology.

The first compendia relating directly the transfer of radionuclides to food and water were in the Congressional hearings cited extensively in chapter 12. These were largely in the 1950s and early 1960s.

An important dilemma that coursed through the discussions of environmental transport in these hearings and elsewhere was whether the amount in food, e.g., milk, was related to the rate of fallout or the total cumulative fallout. This was more than an academic question, since predictions had to be based on one or the other, or perhaps both, and predictions were essential. Proportionality to rate of fallout meant that the food pathway was largely dependent on foliar deposition and subsequent processes. Proportionality to total deposition implied the participation of deposition in and transfer from soil as the principal pathway. Remarks on this dilemma appear in the Congressional hearings, but perhaps one of the broadest earlier discussions was in an AEC report prepared by Harold Knapp (see chapter 12) while he was a member of the Fallout Studies Branch of the AEC Division of Biology and Medicine (Knapp 1961). This concerned ^{90}Sr in U.S. milk and food supplies. Knapp used largely the PHS raw milk sampling network and the AEC Health and Safety Laboratory (HASL) results for the analyses of food and milk, and data from the U.S. Department of Agriculture for soil levels. Unfortunately, his conclusions on the dilemma had to be equivocal.

Meanwhile, the British had stated that, at least in 1958, only about 20% of the ^{90}Sr in British milk could have entered the chain by absorption from the soil. *The rest had to be from foliar deposition.* This was discussed early on by Russell (1960) at the Minneapolis symposium and later in the broad-gauge book already discussed on the whole subject of radioactivity and human diet prepared and edited by Russell (1966).^(a) There was a tendency to attribute most of the cesium content of milk to foliar deposition because of its high tendency to complex with and remain in soil. Thus, deposition rate would be the predictive factor for this and many other relatively immobile radionuclides, and the British so stated. However, for strontium under conditions of longer-term deposition, the potential for some contribution from soil could not be gainsaid. As we are already aware, many factors can influence behavior of an element like strontium in soil, and thus make significant differences in its availability to plants.

(a) To indicate the extent of knowledge as of 1966, as perceived in the United Kingdom, the table of contents of this monograph is given as note 3 at the end of this chapter.

The importance of the foliar deposition pathway, recognized by the British in 1958 and emphasized earlier, was put on a more quantitative basis in later studies of Cataldo and Vaughan (1980) working with plutonium aerosols of less than 1 μm . They subsequently showed that the proportion of airborne plutonium isotopes fixed in bone via the ingestion of vegetables is at least one hundred thousandfold larger by the foliar deposition route than it is by the soil uptake route, when dietary and accumulation factors are considered (Vaughan et al. 1981). One may expect foliar deposition to dominate in food chain routes for other radioelements as well.

In 1962, the U.S. National Academy of Sciences (NAS) produced a report published in pamphlet form that concerned fallout radionuclides in food. It was revised and updated in 1972, with less emphasis on fallout and more emphasis on effluents from nuclear reactors and fuel reprocessing (NAS 1973). It provided summaries of natural and manmade radionuclides in food and a discussion of quantitative methods for gamma-emitting radionuclides in food and the characteristics of various sources of contamination. It urged greater consideration of special groups such as fetuses, infants, the infirm,^(a) and the aged. It also urged further investigation of the reasons for variations in movement of radionuclides in the ecosystems and raised questions regarding the validity of basing human tolerance levels on the sensitivity of the measurement systems.

In 1963, the Federation of American Societies for Experimental Biology held a nutrition symposium on the subject, "Fallout, Food and Man" (Federation Proceedings 1963). The Federation includes essentially all of the disciplines characteristic of the basic sciences in medical schools and frequently has attendance figures up to twenty thousand at its meetings. Robert Menzel, from the U.S. Department of Agriculture at Beltsville, Maryland, reviewed the pathways by which plants can become contaminated with fallout nuclides and considered the quantitative effects of various factors. He pointed out that about 1% of the strontium in surface soil may be taken up by a single crop, while the figure for radiocesium and most of the other fallout nuclides being considered then was 0.1% or less (Menzel 1963). Field work showed that corn, soybeans, oats, or wheat took up from one-third to two-thirds as much radiostrontium when it was placed twenty inches below the surface, as from a conventional plowed layer. Work in England also showed significant differences in uptake as a function of the placement in the soil, especially with reference to the root zone.

At the same symposium, Comar (1963) reviewed factors influencing the biological availability of fallout radionuclides to animals and man. Eisenbud (1963) was careful to point out that, despite emphasis in current thinking on the introduction of manmade radionuclides, naturally occurring radioisotopes, such as ^{40}K , ^{226}Ra , etc., contribute by far the largest portion of radioactivity present in our foods. He pointed out that the uranium and thorium chains together include twenty-five isotopes of ten elements, and it was only in the previous few years that their distribution in foods had been subjected to careful investigation on both sides of the Atlantic.^(b) He also presented summary information on the work of HASL on strontium, cesium, and iodine.

(a) It is to be noted that even present-day transfer models do not include any modifications of input parameters for abnormal physiological or metabolic situations, as might occur in the infirm.

(b) These are mostly alpha emitters and not likely to be confused with fallout radionuclides in environmental measurements, but their transfer processes are pertinent to the general picture.

Read (1963), from the National Dairy Council, discussed countermeasures against fallout in foods. This is beyond our scope here but is mentioned because it constitutes a good summary of the many ideas extant.

The fact that these discussions took place well outside what we have referred to as "the internal emitter establishment" is an important indication of the breadth of talent brought to bear on transfer of radionuclides to foods and water in those years when the basic data behind our present systems were being gathered.

As we pointed out in chapter 12, most of these enterprises wound down in the middle and late 1970s because the levels of fallout in food and other samples were below the limits of detection. The exception is, of course, the long-lived actinides and the discernment of radionuclides from sources such as high-level waste storage areas, uranium mill tailings, etc. However, these are local problems that do not have much bearing on generalized food contamination. The emphasis has changed. The federal establishment must review and help prepare current environmental impact statements for planned facilities. It must review the performance of operating facilities. To do this, competence in the field of environmental transfer factors has had to be maintained. Thus, the *dramatis personae* are now largely in the NRC and the EPA.

The EPA is continuing analyses of samples of air, milk, and water at its Eastern Environmental Radiation Facility in Montgomery, Alabama. The results are issued quarterly in an environmental radiation data report. It will be noted, however, that this effort apparently does not include foods other than milk. An important summary of population doses from many categories of ionizing radiation in the United States was issued by the EPA in 1977 (EPA 1977b). It will be described in more detail in the next section.

In 1972, the EPA issued a guide for environmental radioactivity surveillance. At the time, the EPA viewed surveillance of nuclear facilities as part of its responsibilities and aimed the guide primarily at work outside the plant-site boundary of a light-water-cooled reactor.^(a) While intended as an operating guide, the document presents much information on pathway analysis, generation of models, detection capabilities, and related information that is not usually found in a single document (EPA 1972).

Much current energy is now going into the development of prospective standards for environmental contamination, both in general and for specific elements. We will review some of this effort and its background in the next major section of this chapter.

IV. Population and Environmental Dose Assessment, Resuspension, Standards for the Environment

A prime objective of all the work on environmental transfer factors for radionuclides is an ability to assess the radiation dose to humans or occasionally some other critical segment of the environment. Another objective is to set limits and to be able to measure compliance with those limits. Calculation of dose to populations or individuals in populations has been engaged in rather generally, although many uncertainties prevail. The design of a sophisticated system for

(a) The NRC has primary responsibility for surveillance inside the boundary and there was some dissatisfaction with having EPA set out an independent guide, but the problem seems to have been accommodated. More later.

setting standards for population exposure has remained elusive. We are still leaning mostly on the use of a scaling factor from occupational dosage limits, with the exception of some special cases such as effluents from light-water-cooled reactors, the uranium fuel cycle, and water standards in the environment. In this section, we will review some of the work that has been done in this area by adding some generalized concepts developed over the years and some landmark documents. There is considerable extension from environmental transfer factors *per se* to standards derived for environmental exposures derived in part from these factors.

A. Population Dose Assessment

Population dose assessment is a much older activity than population dosage standards. Obviously, the primary thrust of the fallout measurements in the 1950s and 1960s was assessment of the possible dose to humans or to critical components of the environment. Prior discussions in this and previous chapters have supplied ample illustrations. We refer the reader to chapter 12 for details.^(a) It was a universal effort. The same can be said for the evaluation of the possible impacts of the operation of nuclear facilities (chapter 11). In the late 1960s and early 1970s, there was a veritable explosion of population dose assessments and projections. Part of this came about because of the passage in 1969 by the U.S. Congress of the National Environmental Policy Act and the generation, beginning in 1970, of the need for environmental impact statements for everything from a proposed small facility to the operations of a whole industry. It has been a joint effort of industry and government, with government doing the very large studies, but industry required to do quite complicated analyses for any facility they proposed to build (and there were many of them in those days).

A moderately early example of efforts to estimate population doses from the operation of nuclear facilities in the United States was the so-called "Year 2000" study. The AEC sponsored this study through the Hanford Engineering Development Laboratory with the assistance of the Battelle Memorial Institute and the AEC Division of Reactor Development and the Director of Regulation. It was started in the late 1960s, when nuclear power for electricity was considered the wave of the future, and it concentrated on nuclear power facilities. Plans for nuclear power in a specific area—the upper Mississippi and lower Missouri River Basins—were built into computer codes. Like the more general Lawrence Livermore work cited earlier, exceptional care was taken to include all radionuclides and all associated pathways. The study was issued by AEC as a voluminous and very informative in-house report (AEC 1973). An abridged version was presented by Saul Strauch, of the AEC Division of Reactor Development and Technology, at the Third National Symposium on Radioecology held at Oak Ridge in May 1971 (Strauch 1971). The dose calculation model was, as presented, probably one of the most comprehensive to be included in one document up to its time. It is shown as figure 15.11.

(a) Remember that the concept of dose commitment (chapter 16 and later sections of this chapter) was introduced by UNSCEAR in 1962 from ideas generated by Bo Lindell as a means for evaluating the public health significance of the fallout from nuclear weapons testing.

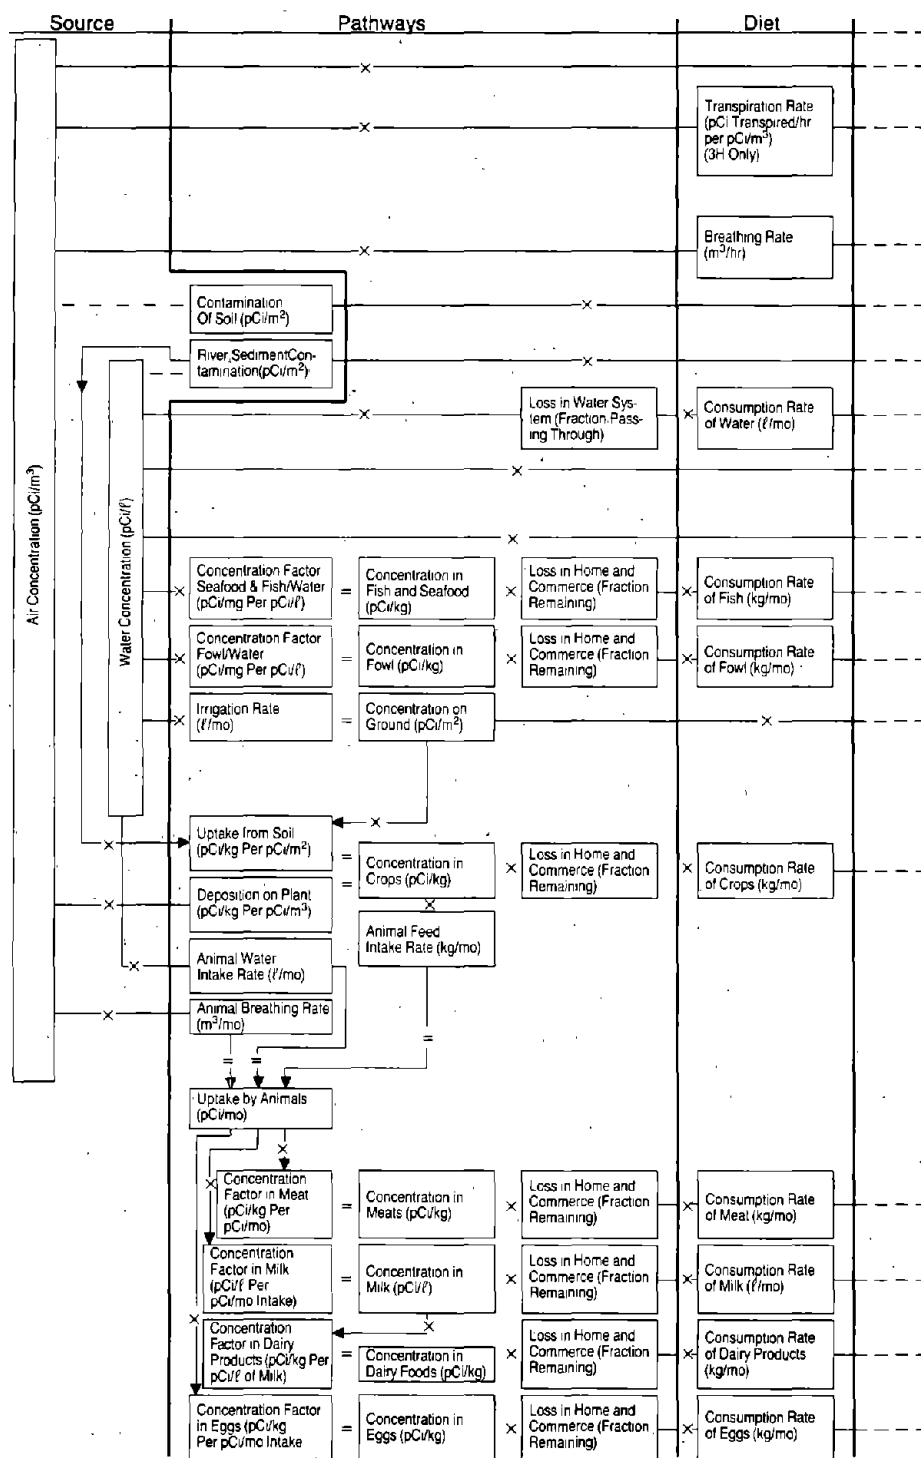

FIGURE 15.11. Dose calculation model. (Redrawn from Strauch 1971.)

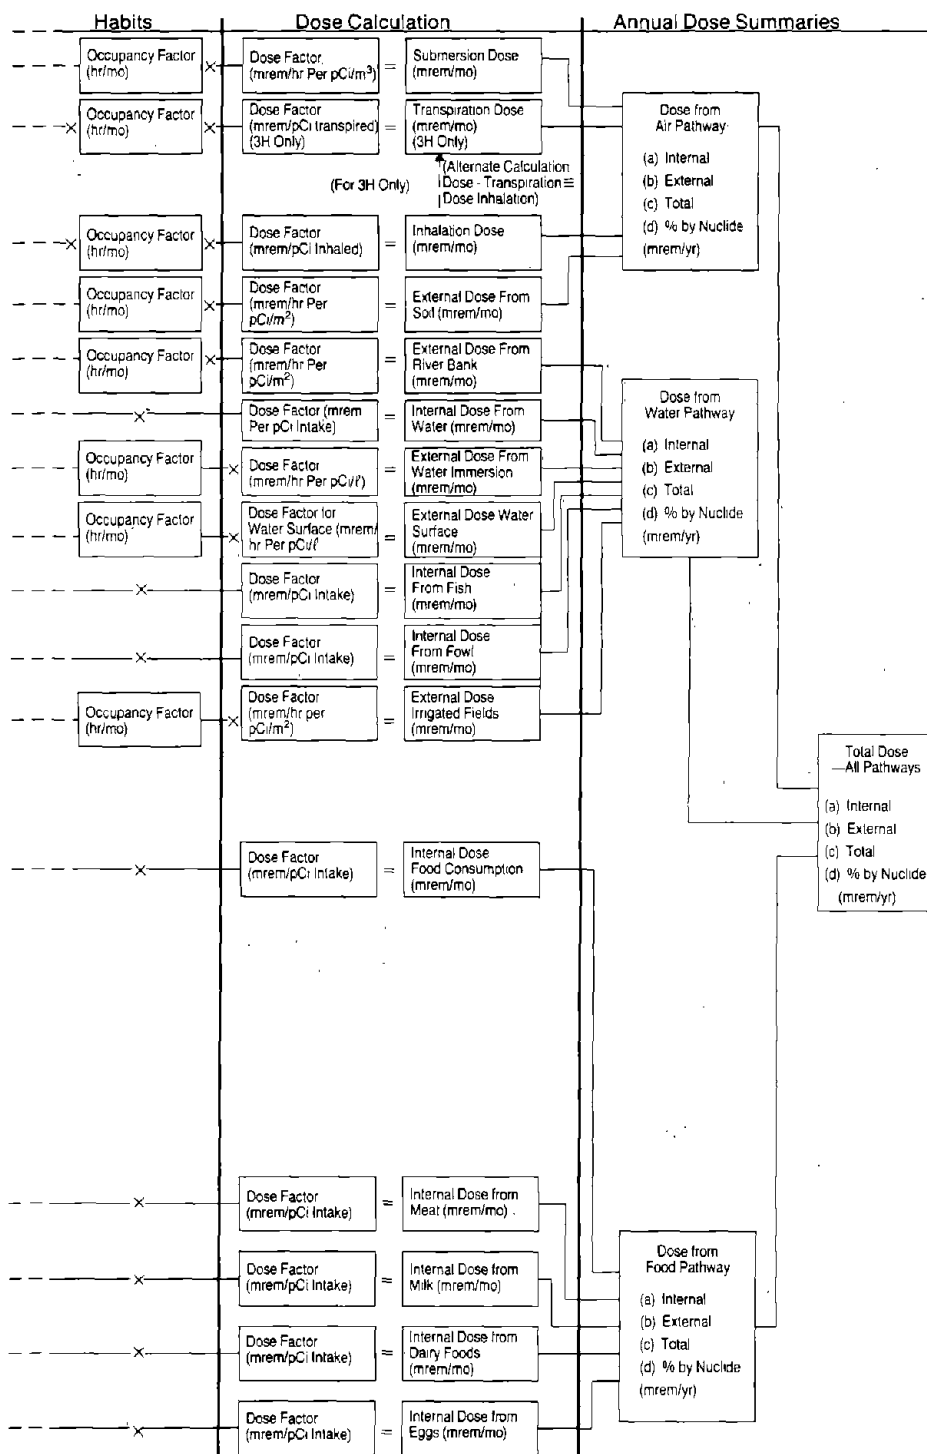

FIGURE 15.11. Continued

In order to get to the source terms, air concentration and water concentration models had to be developed for different reactor types, for processing plants, etc., plus operational factors, a list of food items, a living pattern data flow; in toto, enough to choke the best computers of the day, although no problem for current models. Unfortunately, the quantitative answers from this study are not germane now because the projections for nuclear facilities were far greater than what actually developed. The actual doses will be significantly lower. Nevertheless, the methodology could be applied to revised scenarios, and has been, with modifications, by the currently active agencies. A few of the highlights are presented below:

1. Despite variable contributions to specific organs from specific radionuclides and from more than one pathway, the radiation dose to the population involved was governed to a considerable extent by air transport. Water and food transport played less important roles. The relative contributions of various pathways for total body and six organs are shown as figure 15.12.

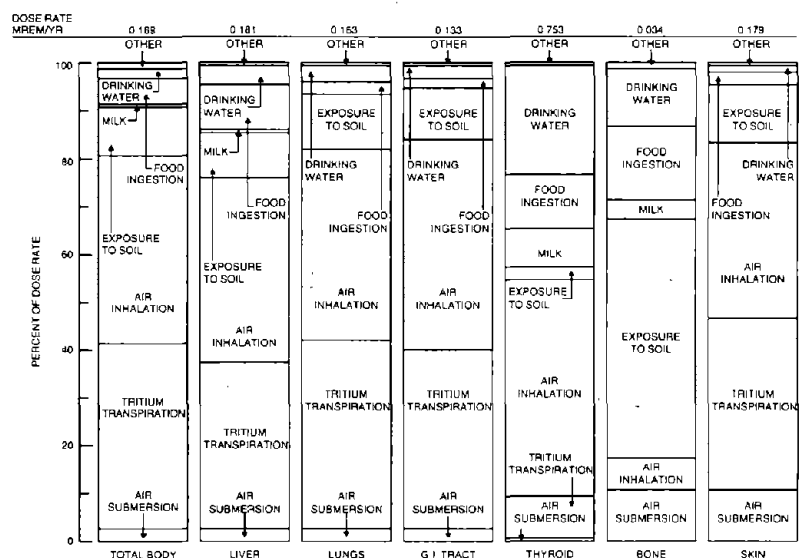

FIGURE 15.12. Contributions by pathways (average individual). (Redrawn from AEC 1973.)

Note that tritium transpiration plays an important role for most pathways and that it is considered an air pathway. The item "exposure to soil" is regarded as external radiation from nuclides deposited in soil.^(a)

2. The contributions from the many nuclides involved are nothing like those seen with fallout or any general exposure to mixed fission products from nuclear facilities. The reason for this is the degree of containment achieved in normal operations. Thus, the noble gases, the iodines, and tritium are the major contributors, except for bone. Indeed, it is only for bone that strontium and ruthenium appear at all. This distribution, by organ system, is shown in figure 15.13.

(a) The apparently large contribution from this source to bone, seen in figure 15.12, is due to the relatively low radiation dose absorbed by bone from the sources dominant in this study and the fact that the values are relative, i.e., percentage of dose rate.

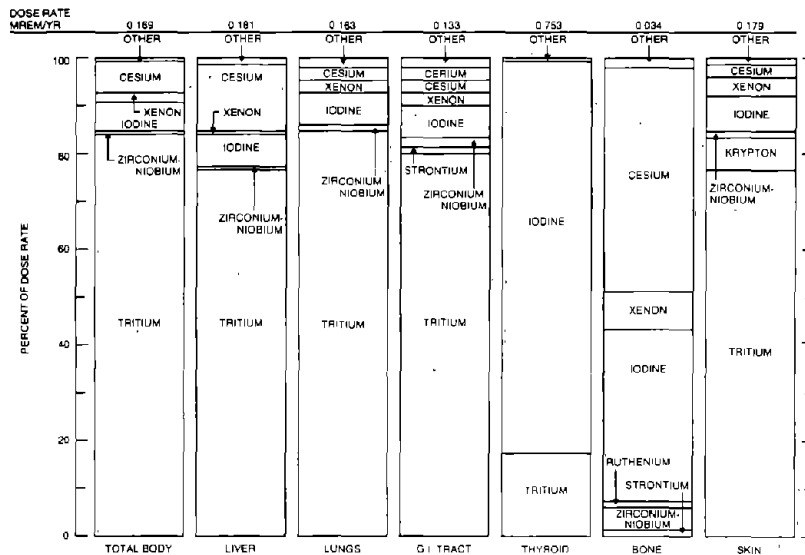

FIGURE 15.13. Contributions by radionuclides (average individual). (Redrawn from AEC 1973.)

It should be understood that this distribution of doses could be entirely different if the study had focused on accidental releases. This was strictly a normal-operation scenario with high factors of containment for most of the "bad actors" seen in fallout or in the release of appreciable fractions of the radionuclides present in a nuclear facility.

3. For bone and thyroid, food and drinking water pathways assumed more importance than for other organs.
4. The generalizations above were for the mix of reactor types projected. To give the reader a base for independent judgment, an elaborate table is included in the report that analyzes the relative contribution of each major radionuclide for different reactor types and for various components of decontamination systems, reprocessing plant operations, etc.

There are a few differences in detail between the full AEC report and the paper by Strauch (1971). They do not modify the principles significantly.

In 1972, the EPA produced a report, *Estimates of Ionizing Radiation Doses in the United States 1960-2000* (Klement et al. 1972). Since this was something of a prologue to a more comprehensive effort published later, we will hold discussion for the present.

The IAEA seminar at Portorož, Yugoslavia, on Population Dose Evaluation and Standards (IAEA 1974) produced a high concentration of workers and papers addressing the general theme of population dose evaluation.^(a)

(a) Because of its applicability to the subject at hand, and to show the extent of the international resources that could be brought to bear, the table of contents of this seminar is shown as note 4 at the end of this chapter.

The dose-commitment approach used for assaying occupational exposure was extended in the early 1970s to population exposure. At the Portorož seminar, Beninson, from Argentina, introduced the term "Collective Dose Equivalent" (Beninson 1974). This was applied to individuals in a group, a subpopulation, or a population. The collective dose was defined as:

$$S = \sum_i D_i N_i$$

where D_i is the dose received by individuals in a group i and N_i is the number of individuals in the group. The answer was in "man-rad" or "man-rem." To get the collective dose *commitment*, an infinite time integral of the average dose rate caused by a given practice or operation multiplied by the size of the population was computed. This was symbolized as:

$$S_C = \overline{\dot{H}(t)} P(t) dt$$

where S_C is the collective dose equivalent, $\overline{\dot{H}(t)}$ is the average dose rate at time t , and $P(t)$ is the size of the population at time t . It was necessary to postulate growth of the population. Beninson postulated exponential growth for the near term at a rate of $2 \times 10^{-2}/\text{yr}$.

Using reasonable assumptions regarding environmental transfer, tissue dosimetry, etc., the collective dose equivalent rates for readily airborne radionuclides were computed. They were relatively large, on a per curie basis, for ^{85}Kr , moderate for tritium, and very low for ^{129}I . The story would have been different if dose commitment rather than dose equivalent rate had been considered, especially over such long integration periods. For example, because of its very long half-life, the dose commitment from ^{129}I would be delivered over many millions of years.^(a) These figures, on a per curie basis, need to be multiplied by source terms such as the release rates per unit of energy generated to give estimates of population dose commitment from the operation of nuclear power facilities, or by measured fallout rates and totals to give estimates of population dose commitment from nuclear testing.

Beninson has been an active member of the ICRP for many years. It is, therefore, not surprising to find that the concept of collective dose equivalent appeared in the revised ICRP recommendations in Publication-26 (ICRP 1977). The quantity was defined, slightly differently than in the Beninson paper at Portorož, as:

$$S = \sum_i H_i P_i$$

where H_i is to *per caput* dose equivalent to the whole body or any specified organ or tissue of P_i members of a subgroup (i) of the exposed population. For a particular practice, with a source (k), the collective dose equivalent was defined as:

$$S_k = \int_0^\infty H P(H) dH$$

where the $P(H) dH$ is the number of individuals receiving a dose equivalent in the range H to $H+dH$.

(a) It will be noted that Beninson chose radionuclides that were easily dispersed in the environment but had from long to very long half-lives. Obviously, an integration to infinity is not very much needed for short-lived radionuclides.

Neither the Beninson paper nor the ICRP definition says much about the environmental dispersion model(s) to put between the source and the final calculation of dose. Apparently, Beninson considered only rapidly dispersing elements and the atmospheric transfer route.

There are few cases where the entire story from release at the source to its final dose commitment is told in equal detail. One moderately complete example can be found in work from Associated Nuclear Sciences in London (Martin and ApSimon 1974). They modeled local doses from a typical U.K. site (probably Windscale) for tritium, ^{14}C , and ^{85}Kr to a standardized critical group, to the U.K. population, and to the global population.

They assumed airborne dispersion and a standard dilution factor of $10^{-7} \text{ sec m}^{-3}$, a 100-m stack, and used Pasquill's methods for calculating dispersion. Of special interest is the twenty-compartment model for ^{14}C they got together for estimating the dose to the global population. This could apply as well to fallout radionuclide dispersion as to a local source and is given as figure 15.14.

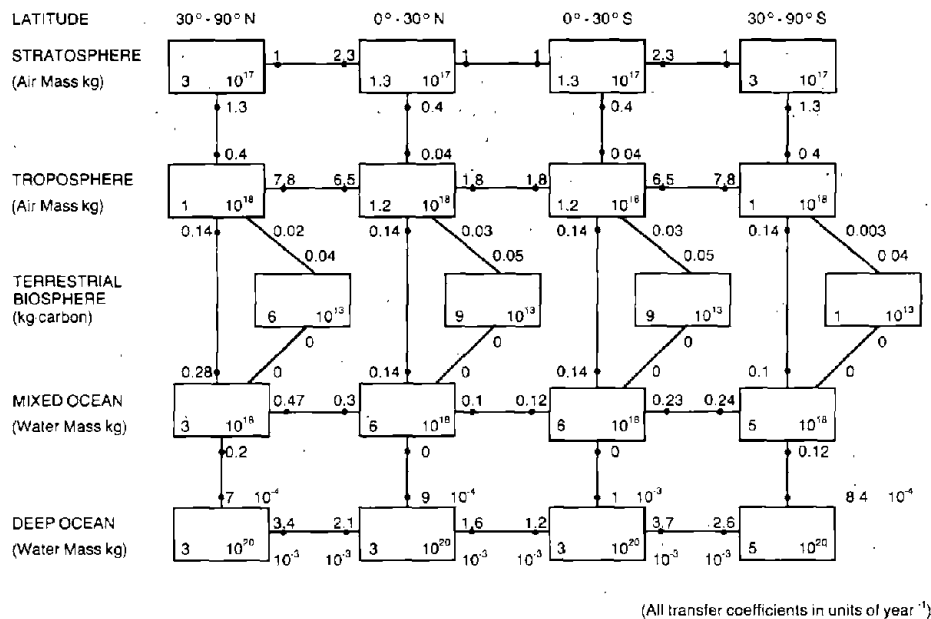

FIGURE 15.14. Global transport model for ^{14}C . (Redrawn from Martin and ApSimon 1974.)

Let us quote the details the authors give about this model.

Four latitude bands are considered, 0° to 30° and 30° to 90°, north and south. Each latitude band is divided into five compartments, namely, stratosphere, troposphere, mixed ocean, deep ocean and a fifth compartment which may represent either the biosphere or surface water. The rates of exchange between atmosphere and ocean or atmosphere and biosphere depend on the physical and chemical form of the contaminant. Within the atmosphere or the ocean, the dispersion of radioactivity depends largely on the natural circulation cycles. The transfer coefficients between the various compartments in the model have been estimated from a review of a number of authors.

In the atmosphere, mixing within each latitude band is quite rapid with time scales of weeks to months. The troposphere is rather shallower at the higher

latitudes than in equatorial regions and mixes more rapidly with the stratosphere. Mixing between the latitudes depends on prevailing wind systems and on Hadley cell circulation. Transfer between the hemispheres takes place both by the mean Hadley cell circulation and by eddies in the upper troposphere.

In the oceanic circulation system, the surface layers down to a depth of 50 to 100 m are well mixed by the influence of winds and surface currents. Residence times in these surface layers are estimated to be a few years. Transfer rates within and from the deep ocean are much slower. During winter in the arctic and antarctic, cold water sinks and a deep water current is induced. The deep water from the arctic flows south at rates as low as one mile per day and resurfaces in the antarctic region. Cold water sinking in the antarctic is even denser and flows underneath the arctic current. Radioactivity penetrating to these deeper layers is likely to remain there for hundreds of years.

(Modified from Martin and ApSimon 1974)

For tritium, they assumed that both ingestion in water and exposure to atmospheric tritium contributed to the dose commitment. They had to modify the atmospheric dispersion model for tritium from that for ^{14}C , not only for the different transfer constants, but because the relative proportion of water vapor in the atmosphere decreases quite rapidly with altitude. Also, tritium is lost from the atmosphere to the land and sea by both rain and dry deposition.

For krypton, the authors could assume simple mixing and circulation in the atmosphere^(a) because of its great insolubility.

The dose commitments from these three radionuclides, using the postulates described in part above, are shown, as calculated, in table 15.9. Note that these figures are per curie of radionuclide released.

TABLE 15.9. Dose Commitments from Unit Releases of H-3, C-14, and Kr-85

Nuclide	Mode of Exposure	Dose Commitment per Ci Released		
		Standardised Critical Group ^(a) (rem)	UK Population ^(b) (man-rem)	Rest of World Population (man-rem)
H-3 Release to Atmosphere	Whole Body	8×10^{-9}	1.1×10^{-2}	3×10^{-3}
	Sea	—	—	2×10^{-4}
C-14 ^(c)	Whole Body	5×10^{-7}	1 (i)	14 (i)
		—	2 (ii)	300 (ii)
Kr-85	Whole Body	1.8×10^{-11}	7×10^{-6}	8×10^{-5}
	Skin	3×10^{-9}	1.3×10^{-3}	1.5×10^{-2}

Notes a. Based on dilution factor of $10^{-7} \text{ sec m}^{-3}$

b. Including first pass and subsequent exposure.

c. Dose commitment to i) 30y, ii) infinity.

Source: Modified slightly and reset from Martin and ApSimon 1974.

In these calculations, the build-up of dose (whole-body average) for ^{14}C from world nuclear power programs goes from 10^{-6} rem/yr in 1970 to about

(a) That is with the air masses in the normal atmospheric circulation system.

8×10^{-4} rem/yr by the year 2020. Then assuming no further release after 2020, there is a gradual decay (in two steps) back to about 8×10^{-6} in 10^4 yr.

Also, in 1974, the EPA produced an approach that they called "Environmental Radiation Dose Commitment." They applied it to the nuclear power industry (EPA 1974). This went beyond radiation dose to include potential adverse health effects. In a sense, the concept can be said to represent irreversible public health commitments. They chose four long-lived radionuclide groups: tritium, ^{85}Kr , ^{129}I , and the actinides (^{238}Pu , ^{239}Pu , ^{240}Pu , and ^{241}Pu ; ^{241}Am , and ^{242}Cm and ^{244}Cm). Theoretically, the total population dose was calculated as the sum of all doses to individuals over the entire time period the material remains in the environment in a state available for interaction with humans. However, they eschewed integration to infinity. Even though some of the radionuclides chosen might persist for up to millions of years and might migrate over quite large areas, the EPA investigators felt they could not meaningfully project their persistence in the biosphere for periods longer than a number of decades. They chose one hundred years. This may well be because they were in a good position to appreciate the problems of long-term extrapolation from our current environmental models. They also chose to consider potential consequences of only the next fifty years of nuclear operations of the U.S. nuclear power industry.

The mathematical expression for the cumulative population dose was not dissimilar from those quoted earlier, except that it had overt terms for a pathway model conversion factor and a dosimetry conversion factor. It is as follows:

$$D_i(t) = \sum_{n=0}^{\infty} Q_i(t) e^{-\lambda_i n} T_i(n) F_i P(t+n)$$

where $D_i(t)$ = cumulative population dose resulting from the release of radionuclide i in calendar year t

$Q_i(t)$ = quantity of radionuclide i released in the year t

λ_i = radioactive decay factor for radionuclide i

$T_i(n)$ = pathway model conversion factor relating quantity of radionuclide i released to its concentration in the medium at the location of interest n years following release

F_i = dosimetry conversion factor relating concentration of radionuclide in the medium to resultant dose to individuals exposed

$P(t+n)$ = number of persons exposed in calendar year $(t+n)$

t = calendar year of release

n = number of years from year t

This illustrative expression is necessarily simplified. In real applications, the complications introduced by the multiplicity of environmental pathways, differences in doses to various organs, and the spatial dependence of both the pathway model and population must be considered explicitly. This expression applies specifically to the situation in which exposure of all individuals is uniform and the dose of interest is to the whole body, or to one organ, and from one medium only. Appendix A contains more detailed general equations, which consider the complications introduced by the above and other factors. (EPA 1974)

For the health effects, they limited themselves to estimates of cancer and serious genetic effects and used risk coefficients from the 1972 NAS BEIR report. As a further exercise, the EPA analysis chose to try two release fractions for the four radionuclides: (1) those associated with what they termed "expected minimum performance," a somewhat confusing term that meant expected normal minimum releases; and (2) a "public health planning" value that ranged from no change to a factor of one hundred higher in the release fractions (see below).

The report is very useful in giving numerical values for all of the key parameters and, in Appendices, the derivations of the conversion factors for pathways and for dosimetry. Again, the results are not quantitatively useful now because the projections were for a much larger U.S. nuclear power industry than we have. Yet, they are informative in principle and for the methodology. Obviously, any recalculations would probably produce lower values because of the lower source-term figures.

Upper estimates for fifty years of operation showed as many as five thousand to twenty-five thousand committed potential health effects over the succeeding one hundred years. Tritium and krypton produced about the same number of projected effects when normal operations and containment were assumed, and were higher than the actinides. However, the actinides overwhelmed the system for future effects when the "public health" set of criteria was applied.^(a) This somewhat startling difference is shown in figure 15.15

FIGURE 15.15. Estimated cumulative potential health effects committed by projected releases from the U.S. nuclear power industry. (Redrawn from EPA 1974.)

The primary reason that tritium and krypton release fractions do not change in the above calculations is that they are not trapped in present nuclear fuel cycle operations, while iodine and the actinides are normally contained to a very considerable extent.^(b) Nevertheless, the EPA workers take the view that

- (a) It is not clear whether or not the public health criteria were a "worst case" situation. The release fraction for tritium and krypton was taken as 1 for both sets of conditions, while those for ^{129}I were 10^{-3} and 10^{-1} , respectively, and for the actinides 10^{-7} and 10^{-5} for release fraction and 10^{-8} and 10^{-6} , respectively for resuspension (per meter). We will discuss resuspension presently.
- (b) Brodsky (1980) has examined the probabilities of intake by humans of materials potentially available from a number of operations and has found a strong tendency for the fractions to be in the neighborhood of 10^{-6} . While this cannot be a universal number (accidents do happen), Brodsky raised the question as to whether or not it was a "magic number" that could be applied fairly generally for release fractions of all but nuclides like krypton, tritium, etc.

the number of potential health effects for ^{85}Kr (figure 15.15) indicate that means should be introduced to trap it, even though they might be very expensive.

Also, in 1974, the East Tennessee Chapter of the Health Physics Society sponsored a midyear topical symposium on population exposures (Hart, Ritchie, and Varnadore 1974). The participants were a representative cross section of individuals and laboratories active in the field. There were sessions devoted to historical development, the contribution of background radiation exposures, medical radiation exposures, nuclear power exposures, exposures from fossil fuels, consumer products, nonionizing radiation, dosimetry, and a public forum on population exposures from nuclear and nonnuclear electric power generation. Among the papers pertinent to our present discussion is a critical appraisal of population health risks from power plant effluents by Andrew Hull from Brookhaven (Hull 1974). It takes the view that the Appendix I reductions of population exposure guidelines are unnecessarily low (see section III E 3 and IV D). There is also a review by Golden and Pavlich from Commonwealth Edison in Chicago of population doses from the operation of the Dresden and other power reactors in their network (Golden and Pavlich 1974); estimates of population doses from LWR fuel cycle facilities in operation, and calculated long-term population dose following cessation of plant operations done by the group at Oak Ridge (Witherspoon 1974 and Witherspoon and Parzyck 1974); and several others.

Toward the end of its existence as a federal agency, i.e., just before it was split into ERDA and NRC, the AEC launched an environmental survey of the uranium fuel cycle. The final report^(a) was issued by the Directorate of Licensing (AEC 1974b). (Yes, it was in 1974!) It added consideration of the environmental aspects of the entire uranium fuel cycle to reviews of applications to build and operate light-water-cooled nuclear power plants. It included the "environmental costs" of mining and milling, production of uranium hexafluoride, enrichment, fuel fabrication, reprocessing of used fuel, management of both high and low-level radioactive wastes, etc. These went into the cost-benefit analysis required for the environmental reports and statements, yet it stuck primarily to dose, not to risk or health effects criteria.

Obviously, these broad views of what was needed for planning, if applied literally and conscientiously, could add immeasurably to the cost and complexity of planning and building a nuclear power plant. They did. The counterpart in other areas would be as if all of the problems of mining of coal or production of oil, their transportation and storage, disposal of ash and flue gases, were folded into the plans for building a fossil fuel power plant. It was an important gesture to the total impact of an industry on the environment and was very complete. (Table S-3 of the report requires several pages simply to summarize the considerations.) However, it cannot help but be viewed as the beginning of a much more complex era for not only the nuclear power industry, but, if fairly applied, to all of industry. The recommendations became a part of the code of Federal Regulations (Part 50) in June of 1974. The EPA picked up the thread and produced a set of standards for the uranium fuel cycle that we will consider in section C of this part.

(a) There was a preliminary report in 1972.

This one step could, if properly implemented, absorb all of the fully trained environmental scientists extant with any knowledge or interest in radioactivity or nuclear energy matters. There were a lot of instant environmentalists generated in those days!

Clearly, 1974 was a banner year for estimates of population dose!

Three years later, probably one of the most complete assessments of population doses from a broad spectrum of sources appeared in an EPA document on the radiological quality of the environment in the United States (EPA 1977b). It was edited by K. L. Feldman, required a dozen in-house individuals to comb the literature, and covered both external and internal radiation sources. It is divided into the following categories:

1. Ambient Ionizing Radiation
2. Technologically Enhanced Natural Radiation (i.e., radiation from naturally occurring radionuclides released or at least disturbed and redistributed from their natural repositories by the work of humans)
3. Fallout
4. Uranium Fuel Cycle
5. Many sources such as other federal facilities, radiopharmaceuticals, medical radiation, occupational and industrial radiation, consumer products, and nonionizing electromagnetic radiation.

In a single summary table, both the individual and population dose from each source is given, broken down into external and internal radiation sources. It is of interest that cosmic radiation and medical radiation turn out to supply the principal external dose to the population, while technologically enhanced natural radiation, especially radon and its decay products, supplies the largest population dose from internal sources. The table is reproduced here as table 15.10.

TABLE 15.10. Summary of Dose Data from all Sources, United States

Source	External		Internal	
	Individual Dose (mrem/y)	Population Dose (person-rem/y)	Individual Dose (mrem/y)	Population Dose (person-rem/y)
Ambient ionizing radiation	—	—	—	—
Cosmic radiation	41-45	9.7×10^6	—	—
Ionizing component	28-35	9.2×10^6	—	—
Neutron component	0.33-6.8	4.9×10^5	—	—
Worldwide radioactivity				
Tritium	—	—	0.04	9.2×10^3
Carbon-14	—	—	1	—
Krypton-85	0.035*	—	—	—
Terrestrial radiation	30-95	—	18-25	—
Potassium-40	17	—	16	—
Tritium	—	—	4×10^{-3}	—
Carbon-14	—	—	1	—
Rubidium-87	—	—	0.6	—
Uranium-238 series	13	—	2-6*	—
Thorium-232 series	25	—	7*	—

TABLE 15.10. Continued
